### 2.3. Sorafenib Enhances TTFields-Induced Apoptosis

### Int. J. Mol. Sci. 2018, 19, x FOR PEER REVIEW 2.3. Sorafenib Enhances TTFields-Induced Apoptosis

6 of 18

To investigate whether sorafenib and TTFields induce apoptosis, we assessed early apoptosis via annexin V and propidium iodide staining. In the two glioblastoma cancer cell lines, 48-h exposure to sorafenib plus TTFields significantly increased the proportion of early apoptotic cells (Figure 3A). Thereafter, we investigated whether sorafenib-enhanced TTFields cytotoxicity resulted from increased PARP cleavage, leading to enhanced apoptotic cell death. We observed increased PARP cleavage in response to combined TTFields and sorafenib treatment when compared to treatment with sorafenib alone (Figure 3B). To determine whether combinatorial therapy induces apoptosis *in vivo*, we evaluated the apoptotic rate using a terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling (TUNEL) assay. Apoptotic cell death was increased upon combinatorial treatment (Figure 3C). We also investigated the association between ROS production and enhancement of TTFields-induced apoptosis by sorafenib. ROS production was more strongly induced upon combinatorial treatment than upon individual treatments (Figure 3D), which may explain the increased apoptotic rate upon combinatorial treatment. These data are consistent with the results of fluorescence microscopy, as shown in Figure 3E.

**Figure 3.** Effects of sorafenib and tumor treating fields (TTFields) on apoptosis in glioblastoma cells.

(A) U373 and U87 cells were exposed to sorafenib (5  $\mu\text{mol/L}$ ) and/or TTFields for 48 h prior to annexin V/PI staining; (B) cell lysates (30  $\mu\text{g}$ ) were immunoblotted with antibodies against cleaved PARP1 and  $\beta$ -actin. #### 2.4. Effects of Sorafenib and TTFields on Autophagic Cell Death

To investigate the anticancer effects of sorafenib and TTFields further, we examined other cellular responses associated with cell death upon sorafenib or TTFields treatment; in particular, we investigated the effects on autophagy, since both TTFields and sorafenib induce autophagy [20,30]. Western blotting revealed that the levels of LC3, a specific marker of autophagosome generation, were increased in cells administered combinatorial treatment (Figure 4A). As shown in Figure 4B, increased accumulation of Cyto-ID Green, an autophagy indicator, was observed around combination-treated U373 and U87 cells. After 48 h of treatment with TTFields plus sorafenib, Giemsa-stained U373 and U87 cells exhibited ultrastructural changes in the whole cytoplasm and membranes, including loss of plasma membrane integrity and distinct vacuole formation, compared to those receiving individual treatments (Figure 4C). This drastic vacuolization of the cytoplasm without apparent loss of nuclear material is consistent with the described macrostructure of autophagosomes. In addition, transmission electron microscopy was used to verify autophagosome formation in cells receiving combinatorial treatment. As shown in Figure 4D, cells administered combinatorial treatment exhibited accumulation of large autophagic vacuoles with a typical double-layer membrane and organelle remnants, whereas only a few vacuoles were observed in cells receiving individual treatments. In addition, mouse xenografts were stained for LC3 to clarify whether sorafenib combined with TTFields could additionally induce autophagy in vivo compared to the individual treatments (Figure 4E). Collectively, our data showed that autophagy contributes to glioblastoma cell death after combinatorial treatment in vitro and in vivo.

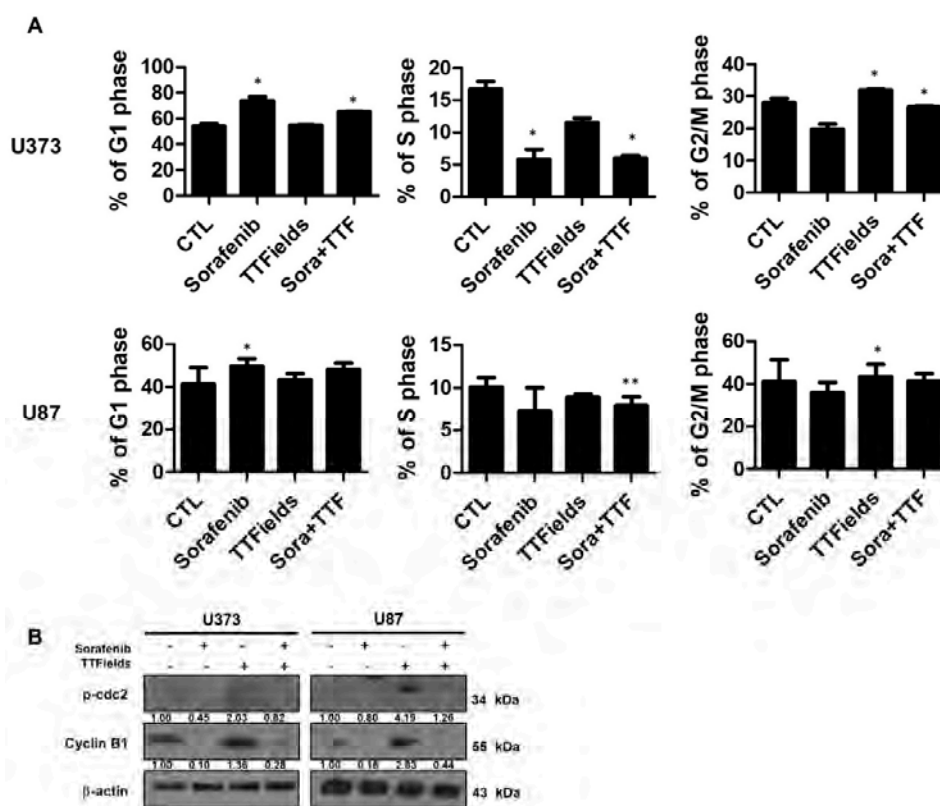

**Figure 4.** Combinatorial treatment with sorafenib and tumor treating fields (TTFs) induces autophagy in glioblastoma cancer cells. (A) cell lysates (30  $\mu$ g) were immunoblotted with anti-LC3 and anti- $\beta$ -actin antibodies. Band intensities were quantified and normalized to actin intensities ( $\beta$  = mean  $\pm$  SD). ## 2.5. Effects of Sorafenib and TTFs on the Cell Cycle

## 2.5. Effects of Sorafenib and TTFields on the Cell Cycle

We analyzed cells treated with 5  $\mu$ M sorafenib or TTFields for 24 h by using propidium iodide staining and flow cytometry to evaluate the effect of sorafenib treatment on cell cycle progression in human glioblastoma cells. Sorafenib treatment increased the proportion of cells in the G1 phase and markedly decreased the proportion of cells in the S phase in comparison with the control treatment (Figure 5A). Similar results were obtained when using U87 cells. When the U373 and U87 cells were exposed to TTFields alone for 24 h, a small fraction of the cells in the G1 and G2/M phases and the percentage of cells in the G1 and S phases also decreased. Upon pretreatment with sorafenib, the TTFields-induced G2/M phase arrest decreased within 24 h after treatment with sorafenib, with an increase in the percentage of cells in the G1 phase compared with that observed with TTFields alone. Western blotting indicated that TTFields alone led to significant accumulation of cyclin B and p-CDC2, which are key regulators of the G2/M transition (Figure 5B). Combinatorial treatment with sorafenib suppressed the TTFields-induced accumulation of these markers.

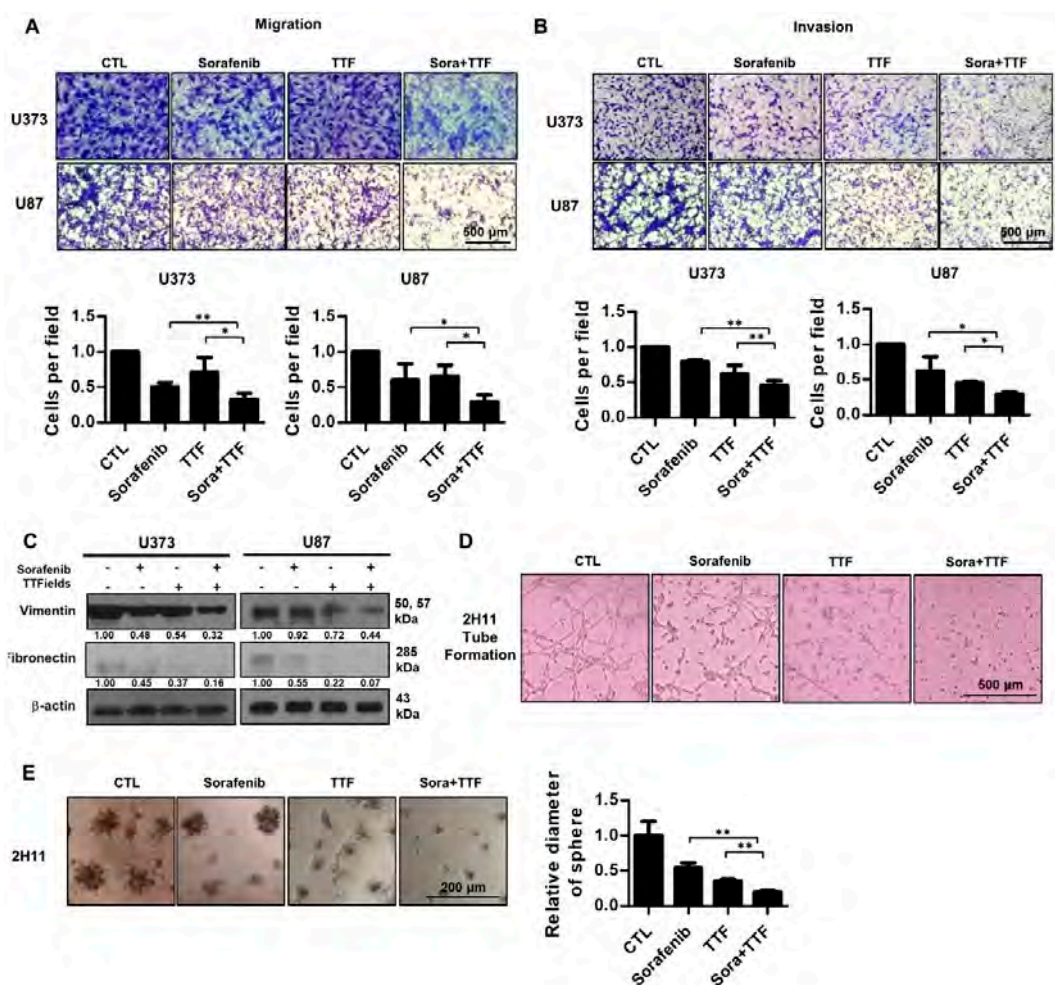

**Figure 5.** Sorafenib plus tumor-treating fields (TTFields) inhibits cell cycle progression in glioblastoma cells. (A) U373 and U87 cells were treated with sorafenib (5  $\mu$ M) and/or 0.9 V/cm TTFields for 24 h. Cell cycle distribution was analyzed quantitatively by flow cytometry (bars: 0.05; 0.05; 0.01; 0.01). (B) phospho-cdc2 and cyclin B1 expression analyzed by Western blotting. Blots were stained as a loading control. Equal amounts of protein (5  $\mu$ g) were electrophoresed and analyzed. Band intensities were quantified and normalized to actin intensities (3 mean  $\pm$  SD).

## 2.6. Combinatorial Treatment Significantly Inhibits Tumor Cell Motility and Invasion and Angiogenesis

To determine whether sorafenib regulates the effects of TTFields on metastasis, we examined the effects of sorafenib and TTFields on U373 and U87 cell migration. A Transwell chamber assay revealed that combinatorial treatment decreased cell migration in the U373 and U87 cell lines after 24 h (Figure 6A). Furthermore, using a Matrigel invasion assay, we investigated whether sorafenib and TTFields could affect the invasiveness of glioblastoma cells. Serum-starved cells were seeded in the upper chambers of the Transwell assay system, and the cells that penetrated the Matrigel barrier

in the upper chambers of the Transwell assay system, and the cells that penetrated the Matrigel barrier in response to a chemoattractant (serum) were counted at various time points. Combinatorial treatment significantly decreased the number of invading U373 and U87 cells as compared to the individual treatments (Figure 6B). Together, these results suggested that sorafenib plus TTFields might effectively inhibit the migration and invasiveness of human glioblastoma cells. To investigate the molecular mechanism underlying the modulation of the expression of epithelial-to-mesenchymal transition markers by combinatorial treatment, Western blotting was used. Vimentin and fibronectin, mesenchymal markers, were downregulated in both cell lines (Figure 6C). Furthermore, we examined whether the combinatorial treatment would block angiogenesis. Combinatorial treatment completely inhibited tube formation in 2H11 cells compared with the individual treatments (Figure 6D); in addition, colonies formed in control 3D 2H11 cell cultures were larger than colonies formed by cells treated with TTFields or sorafenib alone, whereas colonies formed by cells treated with the combination were the smallest (Figure 6E).

**Figure 6.** Effect of combinatorial treatment with Sorafenib and tumor treating fields (TTFields) on the invasiveness and migration of glioblastoma cells. (A) tumor cell migration was assessed using a Transwell chamber assay;  $p < 0.05$ ;  $**p < 0.01$  bar = 500  $\mu$ m; (B) tumor cell invasion was assessed using a Matrigel invasion assay;  $*p < 0.05$ ;  $**p < 0.01$  bar = 500  $\mu$ m; (C) cell lysates prepared from sorafenib-, TTFields-, and sorafenib plus TTFields-treated cells were used in Western blotting using antibodies against vimentin and fibronectin; Band intensities were quantified and normalized to actin intensities ( $n = 3$ , mean  $\pm$  SD); (D) tube formation assay using 2H11 cells subjected to the indicated treatments; (E) 3D colony cultures of 2H11 cells treated as indicated.  $**p < 0.01$ .

### 3. Discussion

This study aimed to investigate the mechanism underlying TTFields sensitization of glioblastoma cells by sorafenib to facilitate the clinical use of sorafenib as a TTFields sensitizer. The Food and Drug Administration (FDA) approved the use of TTFields for recurrent glioblastoma [31]. Recently, a phase III clinical study reported that the use of a combination of 200-kHz TTFields and adjuvant TMZ to treat newly diagnosed glioblastoma enhanced both progression-free and overall survival [31]. Based on this finding, the FDA recently approved the use of TTFields to treat newly diagnosed glioblastoma. While this treatment system is very advanced, to obtain improved clinical outcomes, clinically effective drugs need to be used with TTFields. Among anticancer drugs, we focused on sorafenib, a well-known multikinase inhibitor. The availability of drugs targeting novel cellular pathways has increased the possibility of developing improved treatments for glioblastoma patients. Studies on various angiogenesis inhibitors have highlighted the importance of angiogenesis in cancer growth and progression. Recently, several clinical trials have been initiated to evaluate the use of sorafenib in combination with various anticancer drugs to treat various tumors. The most promising evidence of antitumor activity was observed when sorafenib was combined with interferon- $\alpha$  in renal cell carcinoma, dacarbazine in melanoma, doxorubicin in hepatocellular carcinoma, and gemcitabine in ovarian cancer [24]. Moreover, the combination of sorafenib and another targeted agent, bevacizumab, yielded remarkable antitumor effects in ovarian cancer patients [25], and other clinical studies have reported that the combination of sorafenib and radiation might provide clinical benefits in treating various cancers, including glioblastoma [22,26,27]. However, the mechanism underlying TTFields-mediated enhancement appears somewhat more complex than predicted previously in studies on glioblastoma.

We aimed to provide a scientific rationale for the clinical application of sorafenib as a TTFields sensitizer in glioblastoma treatment. Our results suggest that sorafenib significantly enhances the therapeutic efficiency of TTFields through inhibition of tumor cell survival, apoptosis, cell cycle regulation, autophagy, inhibition of tumor cell invasiveness, and inhibition of angiogenesis in human glioblastoma cell lines. Combinatorial treatment with sorafenib and TTFields inhibited the proliferation of U373 and U87 cells in vitro (Figure 1). Moreover, in nude mice bearing xenografts of U373 glioblastoma cells, combinatorial treatment inhibited tumor growth and prolonged the survival of the animals (Figure 2). Notably, sorafenib at concentrations  $>5 \mu\text{M}$  induced significant cytotoxicity. Sorafenib-treated cells were more sensitive to TTFields than non-treated cells (Figure 1b). These results showed that sorafenib enhanced the sensitivity of U373 and U87 cells to TTFields. Combination with sorafenib significantly enhanced the sensitivity of glioblastoma cancer cells to TTFields by promoting apoptosis via increased ROS production (Figure 3). In addition, sorafenib increased autophagy induced by TTFields (Figure 4). Flow cytometry revealed that treatment with sorafenib, alone or in combination with TTFields, inhibited cell cycle progression (Figure 5). Administration of TTFields with sorafenib significantly decreased invasiveness and angiogenesis (Figure 6).

Despite this combinatorial effect, the critical persistent issue is that the treatment of glioblastoma is complicated by the blood–brain barrier (BBB), which is a physiological obstacle for drug delivery to the central nervous system. The effect of TTFields on the BBB is yet unclear. Various tools have been developed for local drug delivery to brain tumors, including convection-enhanced delivery [32]. Local delivery of sorafenib to malignant cells in the brain may increase the effectiveness of antitumor activity with reduced systemic toxicity. Sorafenib exhibited high tolerability and promising antitumor effects in clinical trials in various types of solid tumors [33–35]. Thus, sorafenib is a potentially promising drug to treat malignant gliomas in combination with TTFields. There is a need for optimizing clinical trials of electric field-based tumor treatments via preclinical testing using patient samples and the application of electric fields alone or in combination with drugs. Furthermore, an ideal TTFields sensitizer enhances the sensitivity of tumor cells to TTFields and is harmless to or protects normal tissue. It is unclear whether sorafenib protects normal tissues in combined treatment with TTFields. However, despite the numerous clinical trials of sorafenib for various solid tumors, interest in clinical

trials on glioblastoma remains low. Patients with glioblastoma, however, have few therapeutic options, with most of these options being palliative. The data produced in this study suggest that the use of sorafenib and TTFields is a valid therapeutic option for treating glioblastoma that warrants further investigation. The efficacy of TTFields has been reported in various cancers, such as non-small cell lung cancer, pancreatic cancer, ovarian cancer, mesothelioma, liver cancer, and glioblastoma [10,36]. Sorafenib is also applicable for treating various cancers, such as renal cell carcinoma, hepatocellular carcinoma, and thyroid cancer [24,25,37]. Therefore, combinatorial treatment with sorafenib and TTFields may be effective for treating various cancers in clinical practice.

In line with our findings, Kessler et al. recently reported that combinatorial use of the spindle assembly checkpoint inhibitor MPS1-IN-3 and TTFields to target glioblastoma cells increased apoptosis as well as the rate of cell cycle arrest [38]. However, sorafenib is an anticancer agent that causes cell cycle arrest in the G1 phase. Therefore, unlike MPS1-IN-3, which increased G2/M phase when administered in combination with TTFields, sorafenib reduced it. In addition, both MPS1-IN-3 and sorafenib promoted apoptosis and suppressed proliferation, suggesting that TTFields may produce synergistic effects with various therapeutic agents.

In summary, we report that sorafenib can increase the sensitivity of glioblastoma cancer cells to TTFields through inhibition of tumor cell survival, apoptosis, cell cycle regulation, autophagy, inhibition of tumor cell invasiveness, and inhibition of angiogenesis. These findings provide a molecular basis for the use of chemotherapeutic drugs as TTFields sensitizers to treat cancer. In the future, the identification of TTFields seems to be key for the optimization of therapeutic strategies for glioblastoma.

#### 4. Materials and Methods

##### 4.1. Experimental Setup for Electric Fields

TTFields were generated with a pair of insulated wires (Seoul Electric Wire Co., Ltd., Chungcheongbuk-do, Republic of Korea; outer diameter, 0.4 mm; polyvinyl chloride insulation thickness, 0.17 mm; dielectric breakdown, 25 kV/mm) connected to a function generator (AFG-2112, Good Will Instrument Co., Ltd., Taiwan) and a high-voltage amplifier (A303, A. A. Lab Systems Ltd., Ramat Gan, Israel) that generated sine-wave signals of 0–800 V [39]. To apply the electric field to cells, the insulated wires were attached to the bottom of each cell dish, 1 cm from each other. The applied electric field intensity and frequency was 0.9–1.5 V/cm and 150 kHz, respectively, for all experiments. To confirm the voltage, the same culture dishes as those used in the in vitro experiments were separately prepared, and the voltages applied to the cells were measured using an oscilloscope (GDS-2102A, Good Will Instrument Co. Ltd., New Taipei, Taiwan), while considering the interference caused by the culture dishes [39]. We maintained the frequency at 150 kHz in this experiment because this reportedly is the optimum frequency for U373 glioblastoma cells (cell line used in in vitro experiments) [39].

##### 4.2. Antibodies and Chemicals

Anti-cleaved PARP (#9541), anti-LC3 (#12741) anti-p-cdc2 (#4139), anti-cyclin B (#4138), anti-vimentin (#3932), and anti- $\beta$ -actin (#3700) were purchased from Cell Signaling Technology (Danvers, MA, USA). Anti-fibronectin (ab2413) was purchased from Abcam (Cambridge, UK). Sorafenib tosylate (marketed as Nexavar by Bayer, Leverkusen, Germany) was purchased from Selleckchem (Houston, TX, US). For in vitro experiments, sorafenib was dissolved in dimethyl sulfoxide to generate a 20 mmol/L stock solution, which was stored at 4 °C until use.

##### 4.3. Cell Culture

Human glioblastoma U87 and U373 cell lines were obtained from the Korean Cell Line Bank (Seoul, Korea). U87 and U373 cells were cultured in Dulbecco's Modified Eagle's Medium (DMEM) supplemented with 10% fetal bovine serum (FBS), glutamine, hydroxyethyl-piperazineethanesulfonic

acid buffer (HEPES), and antibiotics in a humidified incubator at 37 °C under 5% CO<sub>2</sub>. The murine endothelial cell line 2H11 was cultured in DMEM supplemented with 10% FBS in a humidified 10% CO<sub>2</sub> environment.

#### 4.4. Cell Viability Assay

Cells were seeded at a density of 5000 cells/well in a 96-well plate and incubated for 24 h, in accordance with the indicated experimental conditions. To quantify cell viability, an equal volume of culture medium containing EZ-Cytox reagent (EZ3000, Daeillab Service, Chungcheongbuk-do, Republic of Korea) was added to the cells, and the mixture was incubated for 4 h. Cell viability was determined by measuring the absorbance at 450 nm using a Multiskan EX (Thermo Fisher Scientific; Waltham, MA, US).

#### 4.5. 3D Culture System

Human glioblastoma U373, U87, and 2H11 cells were seeded in 96-well plates at a density of  $1 \times 10^4$  cells/well. The 96-well plates had been precoated with Matrigel as a basement membrane by adding 40 µl of Matrigel to each well, followed by incubation at 37 °C for 30 min. Cells were seeded onto the gel in appropriate medium, and the wells were photographed 10 days later.

#### 4.6. Colony Formation Assay

Cells were subjected to TTFields 6 h after sorafenib exposure at a final concentration of 5 µmol/L, after which cells were incubated for 48 h. After 14–20 days, colonies were stained with 0.4% Crystal Violet (Sigma, St. Louis, MO, USA). The plating efficiency indicates the percentage of seeded cells of a particular cell line that formed colonies under specific culture conditions. The survival fraction, expressed as a function of irradiation, was calculated as follows: survival fraction = colonies counted/(cells seeded  $\times$  plating efficiency/100).

#### 4.7. Tumor Xenografts in Nude Mice

A single-cell suspension ( $2 \times 10^6$  cells) was subcutaneously injected into the flanks of 5-week-old BALB/c nude mice (Nara Biotech; Gyeonggi-do, Republic of Korea). When the tumor reached a minimal volume of 100–200 mm<sup>3</sup>, 1 V/cm TTFields, 30 mg/kg sorafenib (three times a week) via intraperitoneal injections, or the combination were initiated and continued for 7 days. Tumor volumes were determined with the formula  $(L \times l^2)/2$  by measuring tumor length (L) and width (l) with a caliper. The sample size was determined to be 5 per group because this number of mice was required to achieve an effect size of 0.85, a significance level of  $\leq 5\%$ , and a power of  $\geq 80\%$  in Student's *t*-test. Mice that desorbed from the electrodes during TTFields treatment were excluded. There was no randomization when animals were allocated to experimental groups. The trial was approved by Korea University Institutional Review Board (KUIACUC-2018-73, 1 June 2018).

#### 4.8. Positron Emission Tomography (PET)/Computed Tomography (CT) Acquisition

A Siemens Inveon PET scanner (Siemens Medical Solutions, Erlangen, Germany) was used for PET imaging [40]. Before <sup>18</sup>F-fluoro-2-deoxy-d-glucose ([<sup>18</sup>F]-FDG) uptake, the mice were warmed using a heating pad. Thereafter, 200 µCi of [<sup>18</sup>F]-FDG was injected into the tail vein, and the mice were anesthetized with 2% isoflurane in 100% oxygen (Forane solution, ChoongWae Pharma, Seoul, Korea). To acquire anatomical images, X-ray CT data for the mice were acquired with full rotation and 180 projection, using the Inveon system. The exposure time was 200 ms, and the estimated scan time was 504 s for X-ray CT. X-ray CT data were reconstructed using Feldkamp reconstruction (L.A. Feldkamp et al., Dearborn, MI, US) with Shepp and Logan filters. The effective pixel size of the reconstructed X-ray CT image was 109.69 µm  $\times$  109.69 µm. Thirty minutes after tracer uptake and acquisition of X-ray CT data, PET data were acquired for 15 min within an energy window of

350–650 keV. The emission list-mode PET data were sorted into 3D sinograms and reconstructed using OSEM2D methods. The pixel size of the reconstructed images was  $0.38 \times 0.38 \times 0.79 \text{ mm}^3$ . All relevant corrections, such as normalization, dead-time correction, and random correction, were performed for all datasets. X-ray CT data were used to delineate the region of interest (ROI). PET and CT images were coregistered using Inveon Research Workplace (version 2.0, Erlangen, Germany) (Siemens Medical Solutions). After coregistration of the CT and PET data, the ROI was delineated on the CT image and included in the PET data. The maximum pixel values within the ROI on the PET image were then measured and converted to radioactivity cpm values, using a predetermined conversion factor. The standard uptake value was determined by measuring the tissue concentration (MBq/mL)/injected dose (MBq)/body weight (g).

#### 4.9. Detection of Apoptotic Cells via Annexin V Staining

After sorafenib exposure, cells were subjected to TTFields and then incubated for an additional 48 h. The cells were washed with ice-cold phosphate-buffered saline (PBS), trypsinized, and resuspended in  $1 \times$  binding buffer (10 mM HEPES/NaOH [pH 7.4], 140 mM NaCl, and 2.5 mM  $\text{CaCl}_2$ ) to obtain a cell density of  $1 \times 10^6$  cells/mL. Aliquots (100  $\mu\text{L}$ ) of the cell solution were mixed with 5  $\mu\text{L}$  of annexin V conjugated with fluorescein isothiocyanate (PharMingen; San Jose, CA, US) and 10  $\mu\text{L}$  of a propidium iodide stock solution (50  $\mu\text{g/mL}$  in PBS) by gentle vortexing, followed by 15 min of incubation at room temperature in the dark. Buffer (400  $\mu\text{L}$ ,  $1 \times$ ) was added to each sample, and the samples were analyzed on a FACScan flow cytometer (Becton Dickinson, Franklin Lakes, NJ, USA). A minimum of 10,000 cells were counted for each sample, and data were analyzed using CellQuest software (version 6.0, BD Biosciences, San Jose, CA, US).

#### 4.10. Western Blotting

After sorafenib treatment, glioblastoma cells were subjected to TTFields and then incubated for 24 or 48 h. Then, the cells were lysed with Radioimmunoprecipitation (RIPA) buffer; proteins were separated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis and electro-transferred to nitrocellulose membranes. The membranes were blocked with 1% (*v/v*) nonfat dried milk in Tris-buffered saline with 0.05% Tween-20 and incubated with the appropriate antibodies. Primary antibodies were used at a 1:1000 dilution; secondary antibodies, 1:5000. Immunoreactive protein bands were visualized via enhanced chemiluminescence (Amersham Biosciences; Little Chalfont, UK) and scanned.

#### 4.11. TUNEL Assay

Tumors were harvested and fixed with 10% neutral-buffered formalin. Deparaffinized sections were incubated with 20  $\mu\text{g/mL}$  protease K for 15 min at room temperature, washed with PBS, and incubated with the TUNEL reaction mixture (Millipore, Burlington, MA, USA) for 1 h at  $37^\circ\text{C}$  in a humidified chamber. The analysis was carried out in a blinded manner.

#### 4.12. Fluorescence-Based Quantification of Intracellular ROS

The fluorescent probe 2',7'-dichlorofluorescein diacetate (DCFH-DA) was used to quantify intracellular ROS. For fluorocytometric analysis, U373 and U87 cells were treated for 48 h with TTFields, sorafenib, or a combination and were loaded with 10  $\mu\text{M}$  DCFH-DA in 5 mL of PBS min at room temperature for 30. Fluorescence was measured using a flow cytometer (Becton Dickinson, Franklin Lakes, NJ, USA). A minimum of 10,000 cells were counted for each sample, and data were analyzed using CellQuest software (BD Biosciences, San Jose, CA, US). In addition, the DCFH-DA-loaded cells were observed under a confocal laser scanning microscope (LSM 880, ZEISS, Oberkochen, Germany).

#### 4.13. Autophagy Assay

Cells were treated, harvested, stained with Cyto-ID® Green detection reagent (Cyto-ID® Autophagy Detection Kit 2.0, Enzo Life Science, Farmingdale, NY, US) and Hoechst 33342 in accordance with the manufacturer's protocols [41], and observed under a confocal laser scanning microscope (LSM 880).

#### 4.14. Giemsa Staining

U373 and U87 cells were treated for 48 h with TTFields, sorafenib, or a combination of both, and Giemsa staining was performed using a kit from Sigma (St. Louis, MO, US) (GS500). Briefly, cells ( $10^4$  cells/well) were seeded in six-well plates and were allowed to adhere overnight on cover slips, followed by treatment with TTFields, sorafenib, or a combination of both. The cells were fixed with 4% paraformaldehyde for 10 min and stained with Giemsa (10% in PBS) for 15 min, followed by washing with tap water. Images were acquired using a Nikon Eclipse Ts2R-FL (Tokyo, Japan).

#### 4.15. Transmission Electron Microscopy

U373 and U87 cells were treated for 48 h with TTFields, sorafenib, or a combination of both and then fixed in 2.5% glutaraldehyde (Sigma; St. Louis, MO, US). A Sorvall MT5000 microtome (DuPont Instruments, MT5000, Columbus, OH, US) was used to prepare ultrathin sections after dehydration. The sections were stained with lead citrate and/or 1% uranyl acetate, and autophagic vacuoles in the cytoplasmic area were quantified using Image Pro Plus software (version 3, Rockville, MD, US).

#### 4.16. Immunohistochemistry

For immunohistochemical analysis, 4- $\mu$ m-thick paraffin-embedded glioblastoma sections were mounted on coated glass slides to detect proteins of interest. Following antigen retrieval and blocking of endogenous peroxidases and nonspecific protein binding, slide sections were first incubated with primary antibodies (anti-Ki67 and anti-LC3 [1:200]; Cell Signaling Technology, Danvers, MA, USA), followed by incubation with horseradish peroxidase-conjugated secondary antibodies. Slides were developed with 3,3'-diaminobenzidine, followed by hematoxylin counterstaining. The analysis was carried out in a blinded manner.

#### 4.17. Flow Cytometry

Cells were cultured, harvested at the indicated times, and stained with propidium iodide (1  $\mu$ g/mL, Sigma, St. Louis, MO, US) in accordance with the manufacturer's protocol. Then, the cells were analyzed on a FACScan flow cytometer (Becton Dickinson, Franklin Lakes, NJ, USA). A minimum of 10,000 cells were counted for each sample, and data were analyzed using CellQuest software (version 6.0, BD Biosciences; San Jose, CA, US).

#### 4.18. Invasion/Migration Assay

Invasiveness was measured in vitro using Transwell chambers, in accordance with the manufacturer's protocol. Briefly, cells were seeded onto the membrane of the upper chamber of the Transwell at a concentration of  $4 \times 10^5$  cells/mL in 150  $\mu$ L of DMEM and were left untreated or were treated with the indicated doses of sorafenib, TTFields, or a combination of both for 48 h. The medium in the upper chamber was serum-free, whereas that in the lower chamber contained 10% FBS as a source of chemoattractants. Cells that penetrated the Matrigel or gelatin-coated membrane were stained with cell stain solution containing crystal violet, supplied with the Transwell chamber assay (Chemicon, Millipore, Billerica, MA, USA), and were photographed after 48 h of incubation.

#### 4.19. Matrigel-Based In Vitro Endothelial Tube Formation Assay

Endothelial cell tube formation was assessed using Matrigel-coated chamber slides, as described previously [42]. The results of each assay were photographed (Nikon Eclipse Ti microscope with a DS-Fi1 camera, Tokyo, Japan) at a magnification of 40 $\times$ , and the total area occupied by endothelial cell-derived tubes in each chamber was calculated using NIS-Elements-Basic Research software (version number) (Nikon; Tokyo, Japan) and was expressed as an angiogenic score.

#### 4.20. Statistical Analysis

Means were compared using Student's *t*-test. Differences were considered significant if the *p*-value was less than 0.05 or 0.01.

# Effects of tumor treating fields (TTFields) on glioblastoma cells are augmented by mitotic checkpoint inhibition

Almuth F. Kessler<sup>1</sup>, Greta E. Frömbling<sup>1</sup>, Franziska Gross<sup>1</sup>, Mirja Hahn<sup>1</sup>, Wilfrid Dzokou<sup>1</sup>, Ralf-Ingo Ernestus<sup>1</sup>, Mario Löhr<sup>1</sup> and Carsten Hagemann<sup>1</sup>

## Abstract

Tumor treating fields (TTFields) are approved for glioblastoma (GBM) therapy. TTFields disrupt cell division by inhibiting spindle fiber formation. Spindle assembly checkpoint (SAC) inhibition combined with antimitotic drugs synergistically decreases glioma cell growth in cell culture and mice. We hypothesized that SAC inhibition will increase TTFields efficacy. Human GBM cells (U-87 MG, GaMG) were treated with TTFields (200 kHz, 1.7 V/cm) and/or the SAC inhibitor MPS1-IN-3 (IN-3, 4  $\mu$ M). Cells were counted after 24, 48, and 72 h of treatment and at 24 and 72 h after end of treatment (EOT). Flow cytometry, immunofluorescence microscopy, Annexin-V staining and TUNEL assay were used to detect alterations in cell cycle and apoptosis after 72 h of treatment. The TTFields/IN-3 combination decreased cell proliferation after 72 h compared to either treatment alone ( $-78.6\%$  vs. TTFields,  $P = 0.0337$ ;  $-52.6\%$  vs. IN-3,  $P = 0.0205$ ), and reduced the number of viable cells (62% less than seeded). There was a significant cell cycle shift from G1 to G2/M phase ( $P < 0.0001$ ). The apoptotic rate increased to 44% (TTFields 14%,  $P = 0.0002$ ; IN-3 4%,  $P < 0.0001$ ). Cell growth recovered 24 h after EOT with TTFields and IN-3 alone, but the combination led to further decrease by 92% at 72 h EOT if IN-3 treatment was continued ( $P = 0.0288$ ). The combination of TTFields and SAC inhibition led to earlier and prolonged effects that significantly augmented the efficacy of TTFields and highlights a potential new targeted multimodal treatment for GBM.

## Introduction

Malignant gliomas are the most prevalent, highly aggressive, invasive, and difficult to treat primary brain tumors in adults. The standard treatment regimen for patients with glioblastoma multiforme (GBM), a World Health Organization (WHO) grade IV glioma<sup>1</sup>, includes microsurgical tumor resection followed by local radiation and chemotherapy with temozolomide<sup>2,3</sup>. However, in spite of this multimodal approach the prognosis is unfavorable with a median overall survival (OS) of around 16 months, a progression-free survival of 6.9 months and a 5-year survival of only 9.8%<sup>4,5</sup>. This is accompanied by

severe deteriorations of the patients' neurological and general conditions that impair their quality of life (QoL). Therefore, more efficient treatment options with lower side effects are urgently needed to improve the outcome of patients.

Tumor treating fields (TTFields) at 200 kHz are a novel approved GBM treatment modality that demonstrated an improved median OS by 4.9 months in newly diagnosed GBM patients with only minor side effects in a clinical phase III trial<sup>6</sup> and no deterioration in QoL<sup>7,8</sup>. These alternating electric fields have a frequency range of 100–300 kHz and a field intensity of 1–3 V/cm. For clinical use they are applied at tumor specific frequencies via ceramic electrodes, so-called transducer arrays, adhered to the shaved scalp of the patient. The therapy compliance was tightly linked to the outcome and

monthly compliance above 75% was associated with higher overall survival<sup>9,10</sup>. In addition, this important development in the treatment of GBM patients, the therapy may be further improved by its combination with synergistic therapies. To identify new facilitating compounds, we had a deeper look into the TTFields' mode of action. TTFields interfere with mitotic processes of cells on subcellular level by inhibition of spindle fiber formation and influencing other dipole macromolecules essential for cell division such as septins, ultimately leading to mitotic catastrophe, which could culminate in cell death<sup>11,12</sup>. Further affected biological mechanisms involve apoptosis, autophagy, DNA repair, and immunogenic cell death<sup>11–13</sup>.

Recently, we showed that the inhibition of the spindle assembly checkpoint (SAC) by a crucial SAC regulator, i.e., the evolutionary conserved protein kinase monopolar spindle 1 (MPS-1, also known as TTK)<sup>14</sup>, efficiently reduces GBM cell proliferation in combination with a spindle toxin<sup>15</sup>. The SAC controls the fidelity of bipolar sister chromatid attachment to functional spindle microtubules, alignment of chromosomes at the metaphase plate and presence of spindle fiber tension to ensure equal sister chromatid segregation to daughter cells during mitosis<sup>16</sup>. Defects in these processes are detected by the SAC, which initiates a mitotic cell cycle arrest by blocking the progression of metaphase to anaphase<sup>16</sup>. A defective SAC results in chromosomal instability, aneuploidy and subsequent tumorigenesis<sup>17</sup>. However, in combination with spindle fiber damaging agents like the chemotherapeutic vincristine, it accelerates mitotic catastrophe, causes cell death and even leads to shrinkage of GBM tumors in a mouse model<sup>15</sup>. Therefore, it sensitizes GBM cells to the effects of antimitotic drugs and we hypothesized that the antimitotic effects of TTFields, partially mediated by disruption of the spindle apparatus, may be facilitated and enhanced by an inhibition of the SAC regulator MPS-1. Here, we investigated if the efficacy of TTFields would be augmented by a combination of TTFields that physically damage the spindle apparatus and chemical inhibition of the SAC, leading to earlier and prolonged effects.

## Results

### TTFields impair cell proliferation most efficiently at 200 kHz in various human glioblastoma cell lines

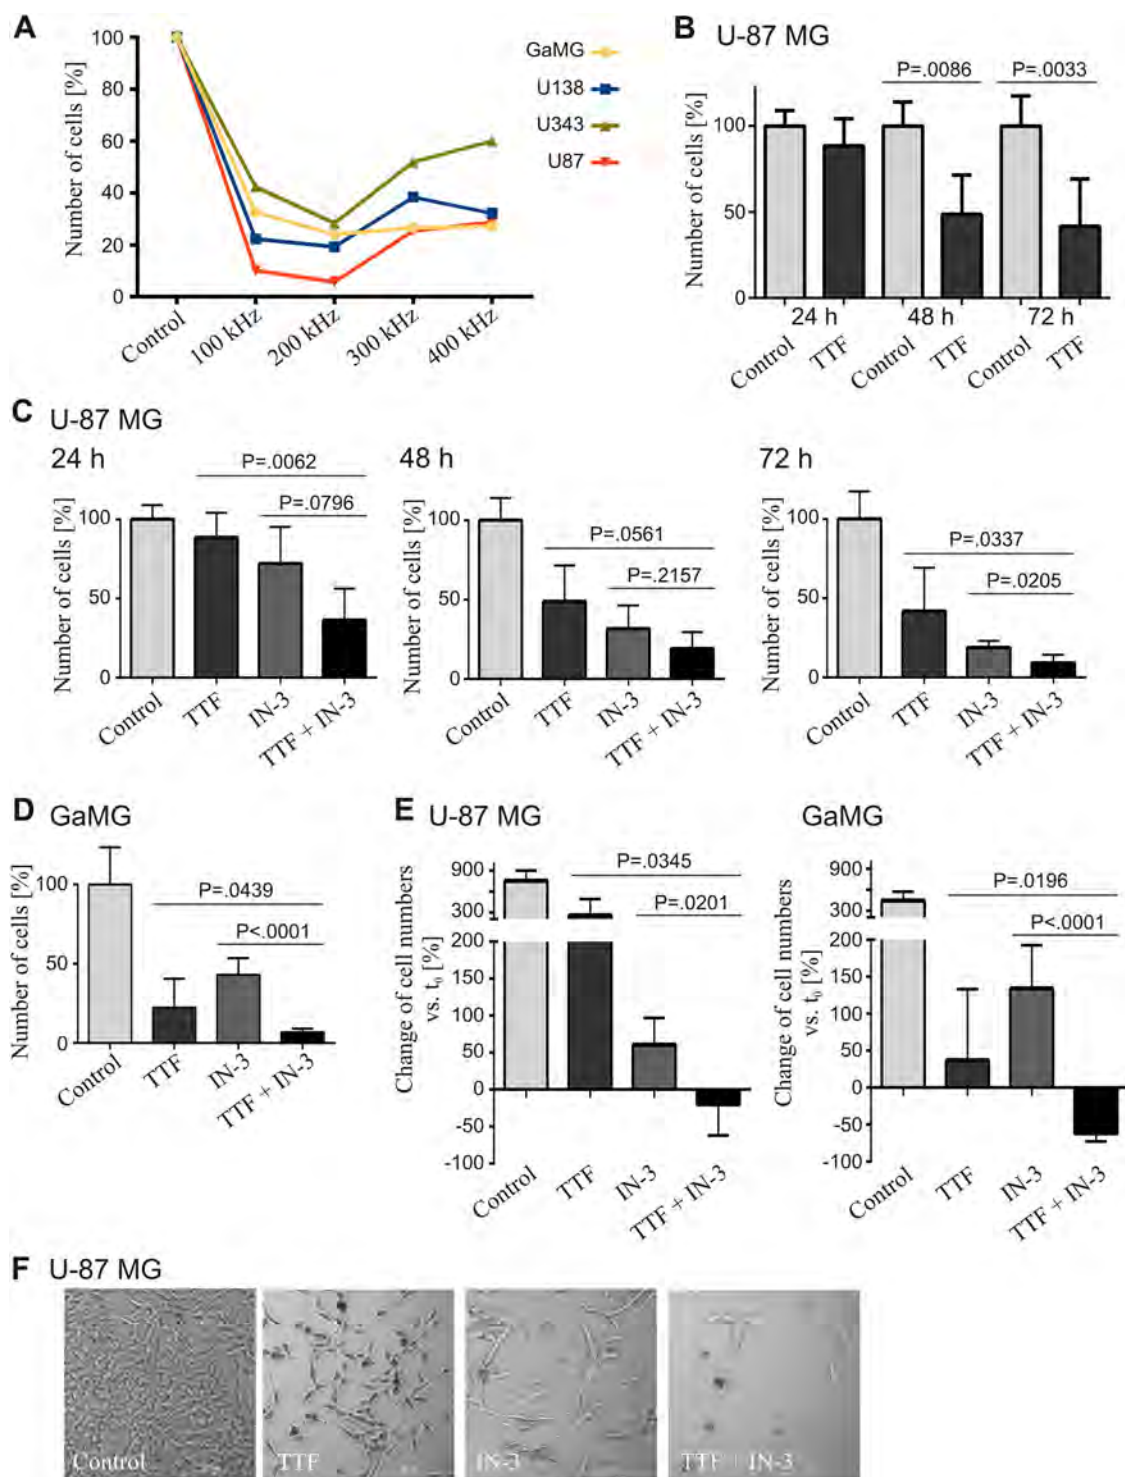

The TTFields frequency necessary to inhibit cell proliferation and to induce cell death is cell size-specific<sup>11,18</sup>. For GBM cells, a frequency of 200 kHz has been established and is applied in the clinical setting<sup>11</sup>. To reproduce these findings and to establish the in vitro technique in the laboratory, frequencies of 100, 200, 300, and 400 kHz were applied for 72 h to the four different human GBM cell lines GaMG, U-138 MG, U-343 MG, and U-87 MG

grown as monolayers on coverslips. Compared to untreated control cells, all tested cell lines responded with a significant reduction in cell proliferation at all analyzed TTFields frequencies, as estimated by cell counts (Fig. 1a). The maximum effect on cell proliferation was observed at 200 kHz, which is in line with previously published data<sup>11,12,18</sup>. Therefore, we proceeded at this specific frequency in all following experiments. U-87 MG cells were treated with TTFields for 24, 48, and 72 h. While there was no effect after 24 h, compared to the control, we observed significantly reduced cell numbers after 48 h (49%,  $P = 0.0086$ ) and 72 h (42%,  $P = 0.0033$ ), respectively, indicating a clear inhibitory effect of TTFields on proliferation (Fig. 1b, Supplementary Fig. 1A).

### The antiproliferative effect of TTFields is enhanced by SAC inhibition

Recently, we developed the SAC inhibitor MPS1-IN-3 (IN-3) and showed that it augments the efficacy of the microtubule destabilizer vincristine<sup>15</sup>. We hypothesized that we could achieve a comparable effect by combining IN-3 with TTFields, because one mechanism by which TTFields disrupts cell division is through the inhibition of spindle fiber formation. Therefore, U-87 MG cells were treated with IN-3, TTFields, or TTFields in combination with IN-3. Cells were counted after 24, 48, and 72 h (Fig. 1c, Supplementary Fig. 1C). There was no effect on cell numbers with TTFields and IN-3 alone after 24 h but an immediate and strong impact was with the TTFields/IN-3 combination. After 48 h of single treatment with IN-3 or TTFields, cell numbers were reduced to 49% ( $P = 0.0087$ , TTFields) and 32% ( $P = 0.0005$ , IN-3), respectively. The combination further decreased the cell numbers to 19% ( $P < 0.0001$ ), each compared to the control. The cell number decrease culminated after 72 h at 9% in the combination compared to TTFields alone (42%,  $P = 0.0337$ ) and to IN-3 alone (19%,  $P = 0.0205$ ) (Fig. 1c, Supplementary Fig. 1C). Similar results were obtained for GaMG cells after 72 h treatment. Compared to TTFields alone, the combined treatment reduced GaMG cell numbers by 69% ( $P = 0.0439$ ) and compared to IN-3 by 84% ( $P \leq 0.0001$ ) (Fig. 1d, Supplementary Fig. 1B). When compared to the 30,000 cells initially seeded, after 72 h U-87 MG control cells on average grew by 754%, while the single treatments grew 256% (TTFields) and 61% (IN-3), respectively (Fig. 1e, left). GaMG displayed similar proliferation with 446% (control), 37% (TTFields), and 135% (IN-3), respectively (Fig. 1e, right). Interestingly, in the combination treatment U-87 MG cell numbers were 19% (Fig. 1e, left) and GaMG cell numbers were 62% lower than the seeded cell numbers (Fig. 1e, right), indicating an even net tumor cell reduction by combining SAC inhibition with TTFields application. This was also confirmed by phase contrast

**Fig. 1** TTFields have antiproliferative effects, which are enhanced by mitotic checkpoint inhibition. Cells were treated with TTFields (TTF) and 4  $\mu$ M of the MPS1 inhibitor MPS1-IN-3 (IN-3) either alone or in combination as indicated. **a** Determination of the optimal TTFields frequency for treatment of GBM cell lines in vitro. TTFields were applied for 72 h and the cells counted ( $n = 1$ ). Totally, 200 kHz appeared to be the optimal frequency and was used for all further experiments. **b** Effect of TTFields (200 kHz) on U-87 MG cell numbers after 24, 48, and 72 h treatment. **c** U-87 MG cell numbers after 24, 48, and 72 h and **(d)** GaMG cell numbers after 72 h single and combined treatments as indicated. **e** Percentage change of U-87 MG (left) and GaMG (right) cell numbers after 72 h treatment compared to the 30,000 cells seeded at  $t_0$ . **f** Phase contrast microscopy of U-87 MG cells after 72 h treatment (representative image of  $n = 3$ ). If not otherwise stated,  $n \geq 3$  independently repeated experiments were performed. SD is shown as error bars

microscopy of U-87 MG cells. In addition to changes in cell numbers, the treated cells appeared to be enlarged and showed an altered phenotype especially in the combination treatment (Fig. 1f).

#### **TTFields in combination with IN-3 causes accumulation of nuclear abnormalities, affects cell cycle and increases apoptosis**

TTFields have been shown to disrupt mitosis and to increase abnormal mitotic figures<sup>11,18</sup>. Indeed, we observed very distinct mitotic figures, especially with the combined treatment, with multipolar spindles and massive chromosomal missegregation in GaMG cells (Fig. 2a). Subsequently, these disturbances lead to abnormal chromosome distribution, aneuploidy, and dysmorphic nuclei, as reported for both TTFields and IN-3<sup>15,19</sup>. Therefore, we quantified the number of abnormal nuclei in U-87 MG cells from the different treatment groups after 72 h (Fig. 2b). Both single treatments significantly increased the numbers of aberrant nuclei (TTFields: 38% and IN-3: 64%, both  $P < 0.0001$ ) compared to the control (9%). The combined treatment led to the highest percentile of abnormal nuclei (73%), which was significantly higher than either treatment alone ( $P = 0.0002$  vs. TTFields and  $P < 0.0001$  vs. IN-3) (Fig. 2b). Further characterization of the cell cycle by FACS analyses clearly showed that the combination of TTFields with IN-3 caused a cell-cycle shift from mainly G1 to the G2/M-phase beyond the effects of the single treatment in U-87 MG (Fig. 2c) and GaMG cells (Supplementary Fig. 1D). In addition, a significant increase of sub-G1 cells was detectable, which most likely were dead cells subject to apoptosis (Fig. 2c, Supplementary Fig. 1D). The combination treatment of TTFields plus IN-3 induced an early stage of apoptosis in 44% of U-87 MG cells, compared to 14% with TTFields alone ( $P = 0.0002$ ), and 4% with IN-3 alone ( $P < 0.0001$ ) (Fig. 3a). These data were confirmed by the TUNEL assay (Fig. 3b), and clearly showed that the inhibition of the SAC can considerably increase the effects of TTFields by enforcing cell death.

#### **SAC inhibition can bridge the interruption of TTFields treatment**

The combination of TTFields and IN-3 showed a more pronounced effect on cell proliferation (Fig. 1c), viability (Fig. 1e), the ratio of dead/alive cells (Fig. 2c), and an increased apoptotic rate (Fig. 3) compared to the single treatments. An inevitable question is the sustainability of the applied treatments, especially whether the strong impact of the combination would translate into persistent and long-lasting effects. Therefore, we evaluated cell numbers after 72 h of exclusive TTFields treatment. Subsequently, the treatment was discontinued (end of treatment, EOT) and the cells proliferation observed for

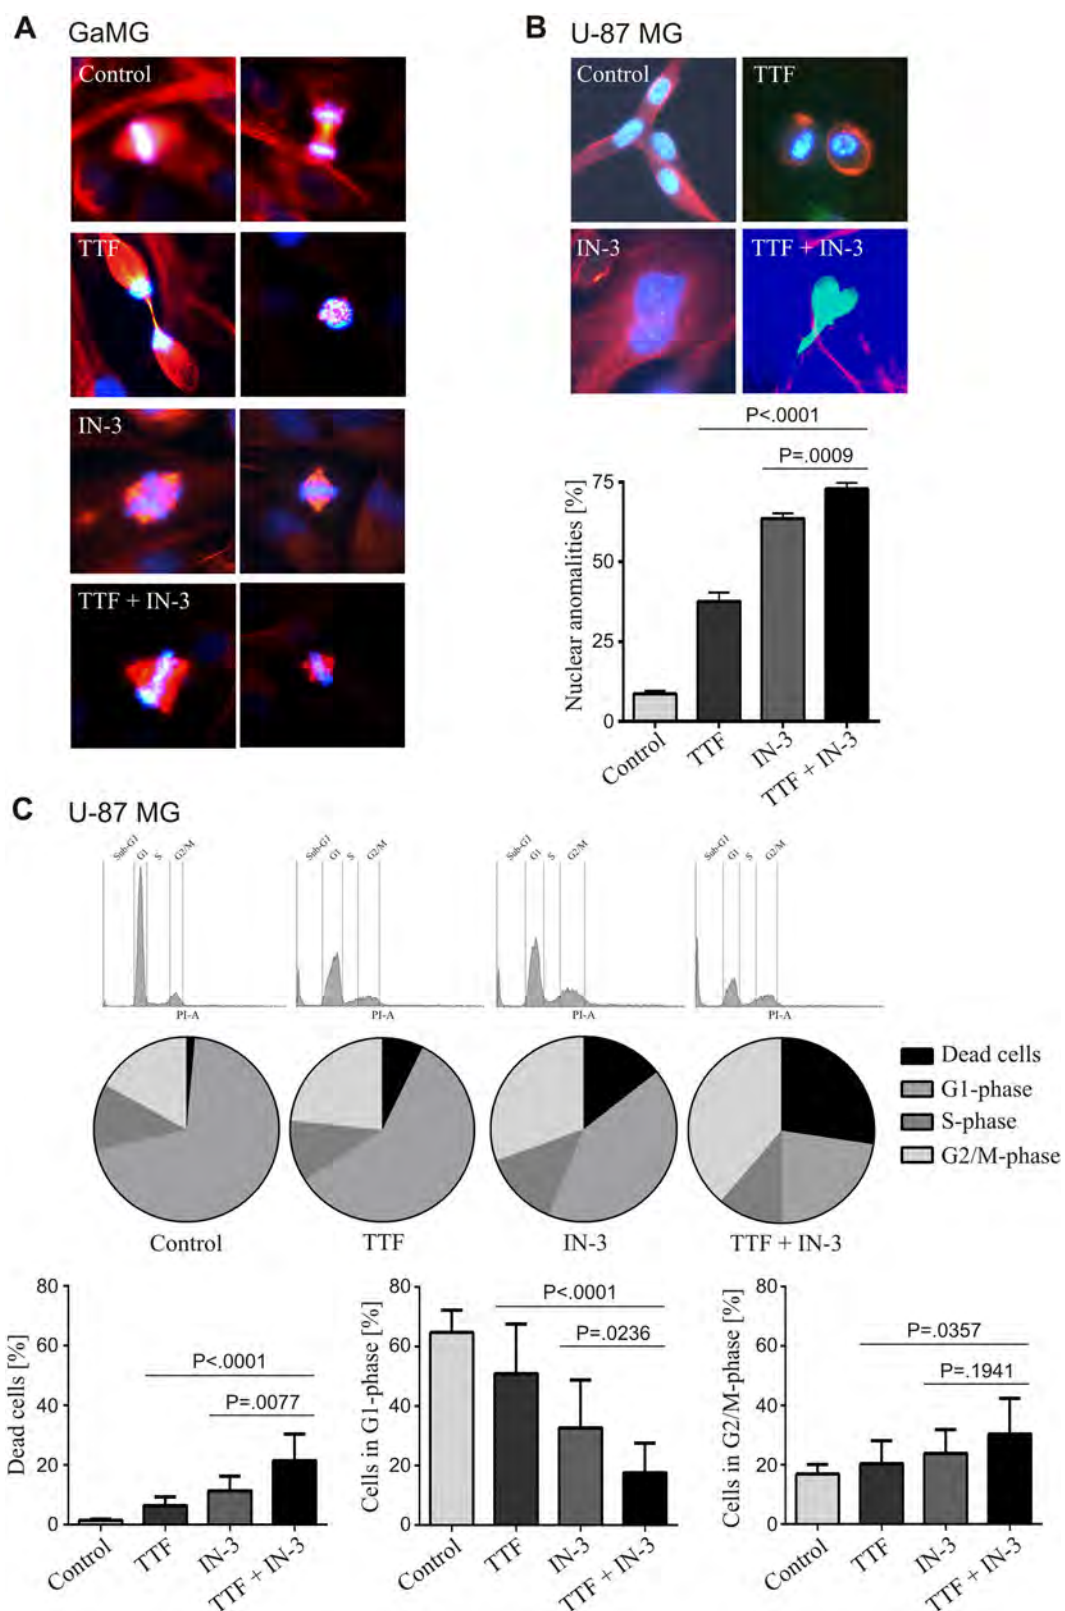

another 24 and 72 h (Fig. 4a). Following EOT, cell numbers decreased significantly to 46% ( $P = 0.0400$ ) during the next 24 h. However, 72 h after EOT the cells had recovered and restarted proliferation. For the treatment solely with IN-3 we found similar results (Fig. 4b). Continued treatment with IN-3 for 72, 96, and 144 h led to a considerably reduced cell number to 59% ( $P = 0.0042$ ), whereas a discontinuation of the IN-3 treatment after 72 h did not cause a further decrease of cells. Surprisingly, continuation of IN-3 treatment after 72 h of combined TTFields plus IN-3 treatment for another 24 and 72 h induced a further reduction of cell numbers down to 8% ( $P = 0.0288$ ). Notably, this effect was stronger than the effect of IN-3 that was given permanently to the cells reflecting a synergism with the clonogenic effect of TTFields even after discontinuation of the latter treatment (Fig. 4c).

#### **Discussion**

GBM therapy urgently needs new treatment approaches that will improve overall survival, while preserving patients' QoL. TTFields are a new therapy approved by the FDA for newly diagnosed and recurrent GBM and are considered a fourth treatment modality that improves overall survival with a minimal impact on patients QoL<sup>6–8</sup>. In the clinical setting, an optimal frequency of 200 kHz has been established for the treatment of GBM, which is in accordance with previously published<sup>11,12,18</sup> as well as our own data derived from cell culture experiments that show that GaMG cells are more sensitive to TTFields than U87-MG cells. The primary mechanism of action for TTFields is the disruption of the normal spindle microtubule assembly by decreasing the ratio between polymerized and total tubulin<sup>12</sup>. Such spindle fiber damage usually activates the SAC and induces cell cycle arrest in the G2/M-phase until the spindle defect is resolved<sup>16</sup>. Prolonged induction of the SAC is the means by which established, chemical microtubule poisons in cancer therapies such as vinca-alkaloids or taxanes work. Prolonged metaphase arrest often causes apoptotic cell death<sup>20–22</sup>. However, one major problem of such therapeutic interventions is that SAC activation and metaphase arrest are not permanent. Cells can escape by a mechanism called mitotic slippage, a mitotic exit without cytokinesis, leading to tetraploid cells. The fate of these cells can be post-slippage cell death by mitotic catastrophe or during a G1-arrest by senescence. Some cells, however, resume proliferation and become aneuploid<sup>23,24</sup>.

Treating cancer cells with TTFields led to an increase of mitotic apoptosis, nuclear abnormalities like polynucleation, micronucleation, and autophagy<sup>12,13</sup>, which are all hallmarks of mitotic catastrophe<sup>23</sup>. These effects were confirmed in our experiments when applying TTFields to GBM cell lines. However, our main objective was to

further improve the treatment efficacy of TTFields by facilitating and enhancing their spindle disrupting effect. This objective was based on our recent observation that inhibition of the SAC key regulator MPS1 by a newly developed inhibitor MPS1-IN-3 (IN-3) in conjunction with the application of the spindle poison vincristine resulted in significantly less cell cycle arrest, and drastic nuclear aberrations, including lobed nuclei, multi-nucleated cells and micronuclei, which reflect gross chromosome segregation defects. In addition, the

combination of IN-3 and vincristine led to almost complete tumor shrinkage and prolonged survival in orthotopic GBM mouse models<sup>15</sup>. Therefore, we concluded that selective MPS1 inhibition sensitizes GBM cells to the effects of antimitotic drugs, an assumption supported by data reported by other groups<sup>25–28</sup>.

Indeed, our data provide evidence that a combination of MPS1 inhibition and TTFields treatment of GBM cells elicited more than just additive effects. The anti-proliferative benefit of the combination treatment started

**Fig. 4** SAC inhibition prolongates TTFields-effects in U-87 MG cells. **a** Experimental scheme. Application of TTFields (gray background) and IN-3 is indicated in blue and was maintained either alone or in combination for 72 h. TTFields application was ended (EOT red) and cells cultured for another 72 h either with (IN-3, blue) or without (w/o IN-3, red, dotted line) IN-3. Cells were counted after 72, 96, and 144 h overall culture, as indicated. **b** TTFields were applied to U-87 MG cells for 72 h and then switched off. The cells' proliferation was determined by cell counting at treatment end (0 h, 100%), and 24 and 72 h after end of TTFields application (w/o TTF, red). U-87 MG cells were incubated with 4  $\mu$ M IN-3 for 72, 96, and 144 h (IN-3, blue) and counted or incubated with IN-3 for 72 h, further cultivated for 24 and 72 h without IN-3 (w/o IN-3, red, dotted line) and then counted. **c** For combined treatment, TTFields were applied to U-87 MG cells for 72 h and then switched off (w/o TTF, red), while 4  $\mu$ M IN-3 was present for 72, 96, and 144 h, respectively (IN-3, blue) or cells were cultured for 72 h with TTFields and 4  $\mu$ M IN-3 and then TTFields were switched off and IN-3 was removed, while the cells were further cultivated for 24 and 72 h after end of treatment (red, dotted line). Experiments were independently repeated with  $n \geq 3$ . SD is shown as error bars

after 24 h, while the single treatments only began to be effective after 48 h. This reflects an acceleration of the comparably slow effect of TTFields action, which is dependent on the direction of the cell axis and the cell division rate<sup>11,12,18</sup>. Importantly, the combination treatment was the only one causing a net reduction of cells below the seeded cell number, while all other treatments only throttled cell proliferation. Whereas the latter findings were in line with published data on TTFields<sup>11,18</sup> and MPS1 inhibitors<sup>29,30</sup>, the former discovery is a novel finding indicating that the combination may increase cell death by mitotic catastrophe, an assumption confirmed by cell cycle analysis, immunofluorescence imaging and apoptosis assays. Thus, these findings may open new perspectives for the treatment of GBM patients by augmenting the TTFields efficacy.

The compliance with TTFields therapy in the clinical trials was tightly linked to the survival outcomes; monthly compliance above 75% was associated with higher overall survival<sup>9,10,31</sup>. Our cell culture experiments revealed that the surviving cells recover with a delay of 24 h after end of TTFields application. This observation suggests that interruption of TTFields treatment for 24 h may still be bridged by the repercussion of the therapy<sup>11</sup>, whereas a treatment break of more than 24 h would result in resumed tumor growth. Therefore, longer treatment breaks should be

avoided to allow optimal clinical outcome. Nevertheless, there are circumstances that inevitably lead to discontinuation of the therapy, e.g., skin irritations<sup>32,33</sup>. It would be of clinical importance to determine if such treatment breaks could be bypassed. After treatment with TTFields and IN-3 for 72 h the cell numbers further decreased considerably at 72 h after terminating TTFields application, indicating a persisting effect when applying the MPS-1 inhibitor. Therefore, such a combination could potentially bridge short breaks and ease the everyday life of patients at same or even better efficacy.

Taken together, the combination of TTFields with the chemical inhibition of SAC was able to reduce GBM cell proliferation, increase apoptosis and could potentially serve as a bridge for TTFields therapy interruption in the clinical setting. Recently, several potent MPS1 inhibitors have been developed<sup>26,34–36</sup> and two of them, BAY1161909 and BAY1217389, are currently in phase I clinical trials<sup>27,37</sup>. Our data provide a rationale for the future clinical evaluation of combined therapies utilizing TTFields and MPS1 inhibitors in patients with GBM.

## Materials and methods

### Cell lines, cell culture and TTFields application

The human GBM cell lines U-87 MG, U-138 MG, and U-343 MG were purchased from Cell Lines Service (CLS,

Eppelheim, Germany). The cell line GaMG was obtained from the Leibniz Institute DSMZ-German Collection of Microorganisms and Cell Cultures (DSMZ, Braunschweig, Germany). Cells were grown as reported elsewhere<sup>38</sup> in 75 cm<sup>2</sup> flasks (Corning, New York, NY, USA) at 37 °C in an atmosphere of 5.0% CO<sub>2</sub> and 100% humidity.

Novocure's *in vitro*<sup>TM</sup> laboratory research system for the treatment of cancer cells was used to administer TTFields to GBM cells *in vitro* as described by Porat et al.<sup>39</sup>. In brief, 24 h before start of TTFields application, cells were trypsinized and plated by placing 350 µl medium containing 30,000 cells as a drop in the center of a glass coverslip (20 mm in diameter) (Hartenstein, Würzburg, Germany) within an *in vitro* ceramic dish (Novocure, Haifa, Israel). After 20 h incubation at 37 °C and 5.0% CO<sub>2</sub> to allow the cells' adhesion, the medium was removed and the plates were filled with 2 ml fresh medium and 2 ml medium containing 4 µM of MPS1-IN-3 (IN-3) (Sigma-Aldrich, St. Louis, MO, USA), respectively. The ceramic dishes were placed onto a base plate connected to a TTFields generator. Each ceramic dish contains two pairs of electrodes perpendicular to each other. A sinusoid function generator and an amplifier integrated into the *in vitro* system generate alternating electric fields<sup>13</sup>. The medium was renewed every 48 h.

#### Cell counting

TTFields were applied for up to 72 h. To evaluate their effects, cells were trypsinized after 24, 48, and 72 h of TTFields application as well as 24 and 72 h after ending TTFields treatment (EOT) by removing the medium, washing with phosphate-buffered saline (PBS) (Biochrom, Berlin, Germany) and adding 0.5 ml Trypsin/EDTA solution (Gibco, Eggenstein, Germany)<sup>39</sup>. The reaction was stopped by adding 1 ml of medium to each plate and cells were counted utilizing the Scepter 2.1 cell counter (Merck, Darmstadt, Germany).

#### Fluorescence immunocytochemistry

Cells grown on coverslips were washed with PBS and fixed in 4% (vol/vol) paraformaldehyde (Merck, Darmstadt, Germany) in PBS for 30 min at room temperature. Cells were rinsed three times with 70 µl TBST (50 mM Tris (Roth, Karlsruhe, Germany), 150 mM NaCl (Merck, Darmstadt, Germany), pH 8.0, 0.5% (vol/vol) Tween-20 (Sigma-Aldrich, St. Louis, MO, USA)) permeabilized and blocked in 70 µl blocking solution (10% (vol/vol) goat serum (Jackson, West Baltimore Pike, USA), 1% (wt/vol) BSA (Serva, Heidelberg, Germany), 0.05% (vol/vol) Triton-X 100 (Sigma-Aldrich, St. Louis, MO, USA) in PBS) for 30 min at room temperature. Totally, 70 µl primary antibody mixture of rabbit anti  $\gamma$ -tubulin diluted 1:1000 and mouse anti  $\alpha$ -tubulin diluted 1:2000 (both from Sigma-Aldrich, St. Louis, MO, USA) in 1% (wt/vol)

BSA, 0.05% (vol/vol) Triton-X 100 in PBS, were added to each cover slip and incubated over night at 4 °C for immunocytochemistry. The cells were washed three times with 70 µl TBST and blocked for 30 min at room temperature in 70 µl blocking solution before they were incubated in the dark with the secondary antibody mixture Cy2-goat-anti rabbit diluted 1:50 and Cy3-goat-anti mouse (both from Jackson, West Baltimore Pike, USA) diluted 1:100 in 1% BSA, 0.05% Triton-X 100 in PBS. After 2 h incubation at room temperature cells were washed three times with 70 µl TBST. Cover slips were mounted to glass slides using fluoromount aqueous mounting medium containing DAPI (Sigma-Aldrich, St. Louis, MO, USA), dried over night at room temperature and stored for 24–48 h at 4 °C. Cells were viewed on an inverted fluorescence microscope LEICA DMI 3000 B. 100 nuclei of each treatment group were inspected and the ratio of aberrant to normal nuclei was calculated. Images were captured through a 100× objective by using the LEICA DFC450 camera and LAS V4.5 software (all Leica, Wetzlar, Germany).

#### Cell cycle analysis and apoptosis assays

After 72 h of TTFields treatment, floating cells from the medium were harvested by centrifugation at 230×g and adherent cells were dissolved by trypsinization. Both cell populations were washed once with 5 ml ice cold PBS, combined and finally resuspended in 500 µl PBS.

For cell cycle analysis the cells were fixed in 4 ml ice cold 70% ethanol (J. T. Baker, Deventer, The Netherlands) and stained with propidium iodide (Sigma-Aldrich, St. Louis, MO, USA). Analysis of the DNA content was performed by flow cytometry (BD FACS Canto 2.0, Becton-Dickinson, Franklin Lakes, NJ, USA) and evaluated with Flowing Software 2.5.1 (University of Turku, Finland).

To measure cell death by Annexin V staining, PBS-washed cells were incubated for 15 min in 500 µl binding buffer (0.01 M HEPES pH 7.4 (Roth, Karlsruhe, Germany), 0.14 M NaCl, 2.5 mM CaCl<sub>2</sub> (both from Merck, Darmstadt, Germany) in PBS), 10 µl propidium iodide (Sigma-Aldrich, St. Louis, MO, USA) and 5 µl FITC-Annexin (Becton-Dickinson, Franklin Lakes, NJ, USA), at room temperature. Within 1 h measurements were performed by flow cytometry (BD FACS Canto 2.0, Becton-Dickinson, Franklin Lakes, NJ, USA). For cell death analysis by TUNEL assay, ethanol fixed cells were stained using the TUNEL Assay Kit—In situ Direct DNA Fragmentation (Abcam, Cambridge, UK) according to the manufacturers protocol. Photographs of stained cells were taken using the LEICA DFC450 camera mounted to a LEICA DMI 3000 B fluorescence microscope and LAS V4.5 software (all from Leica, Wetzlar, Germany). Apoptosis was quantified by counting DAPI and Alexa stained cells using ImageJ<sup>40</sup> and calculating the DAPI/Alexa ratio.

## Statistical analysis

All experiments have been repeated independently at least three times, except for the test of the optimal TTFields frequency, which has been done only once as a proof of already published data<sup>11,12,18</sup>. Statistical analysis was performed using GraphPad Prism 6 Software (GraphPad Software Inc., San Diego, USA). Statistical significance was defined by unpaired two tailed Student's *t* tests and ANOVA, as applicable. *P* < 0.05 was considered to be significant.

## Acknowledgments

We are very grateful to Tcholpon Djuzenova and Bülent Polat (University of Würzburg, Department of Radiation Oncology, Würzburg, Germany) for allowing us to use their FACS analyzer. We thank Elisabeth Karl and Siglinde Kühnel (University of Würzburg, Department of Neurosurgery, Würzburg, Germany) for technical assistance. The in vitro<sup>™</sup> laboratory system has been provided by Novocure. Inc. and the work was supported by the Familie Mehdom Stiftung.

## CNS CANCER

## TTFields improve survival

Glioblastoma is the most common and aggressive form of primary brain tumour, with median overall survival durations in clinical trials of <17 months emphasizing the need for more effective therapy. In 2015, promising interim results of a phase III trial were reported for a novel non-invasive, non-pharmacological treatment modality termed tumour-treating fields (TTFields). The final results have now been published.

TTFields involves the continuous delivery of low-intensity, intermediate-frequency (200 kHz) alternating electrical fields to the tumour using a portable generator connected to a transducer cap worn on the patient's scalp. These electrical fields have been shown to cause mitotic arrest, disrupt organelles, and induce apoptosis selectively in rapidly dividing cells, such as glioblastoma cells.

In the trial, 695 patients who had undergone surgery for glioblastoma followed by concomitant chemoradiotherapy were randomly assigned (2:1) to receive TTFields plus temozolomide or maintenance temozolomide alone. Uninterrupted use of the TTFields device for  $\geq 18$  h per day was recommended and could be continued until second radiographical progression, together with second-line therapy (which in both arms was offered per local practice).

The median progression-free survival from randomization was 6.7 months with TTFields versus 4 months with temozolomide alone (HR 0.63;  $P < 0.001$ ). Moreover, overall survival was also improved by addition of TTFields to maintenance therapy: median 20.9 months versus 16 months (HR 0.63;  $P < 0.001$ ). In an exploratory analysis, 5-year overall survival was 13% versus 5% ( $P < 0.004$ ). Of note, the baseline patient characteristics, including MGMT-promoter methylation status (which correlates with the effectiveness of temozolomide), were well balanced between the treatment arms; TTFields was associated with longer survival in all *post hoc* subgroups.

Importantly, this treatment approach seemed to be well tolerated by patients, and the profile and frequency of adverse events were similar in both treatment arms. However, localized skin toxicities were observed only with TTFields, at the device site (52% grade 1–2, 2% grade 3). Together, these findings support the utility and safety of TTFields in the treatment of glioblastoma.

Kong. Beyond the chemotherapy for brain tumor in neuro-oncology practice. J Neurol Clin Neurosci. Oct 2018;2(3):16.

## Are Neurologists Ready to See the Patients wearing Optune Electric Cap?

Glioblastoma (GBM) is the most malignant brain tumor in adults. Since 2005, newly diagnosed GBM has been treated with surgery, radiation and adjuvant chemotherapy with temozolomide [1]. The standard therapy applied by neuro-oncologists for GBM patients is to provide the chemotherapy agent called temozolomide, to manage seizures and other complications from treatment and disease. With the above aggressive treatment, newly diagnosed GBM has only had a limited median overall survival time of 14.6 months. In 2011, the FDA approved the tumor-treating fields (TTFields) device, Optune (also called Novo TTF) for recurrent GBM [2] after the study showed a non-inferior effect of Optune to “best standard chemotherapy” chosen by doctors. Optune is a portable, battery-operated device that generates electric fields and is worn by the patients on their head like a cap for the treatment of supratentorial brain tumor. Some patients call it an “Electric Cap.” The mechanism is to produce alternating electric fields to interfere with highly charged macromolecules and organelles in rapidly dividing cancer cells to disrupt their neat alignment during the phase of mitosis.

In 2015, FDA approved Optune for newly diagnosed GBM after an EF-14 clinical trial found a positive outcome for patients with brain cancer [3]. In 2017, Optune became part of the NCCN guidelines in the treatment of newly diagnosed GBM [NCCN Guidelines®] [4]. The trial randomized 695 patients with a 2:1 ratio of Optune arm (446) to control arm (229). Both arms were treated with concurrent chemotherapy and radiation therapy followed by adjuvant chemotherapy. Then the trial arm wore the device Optune on head and received adjuvant chemotherapy while the control group only received adjuvant chemotherapy. With the addition of Optune to chemotherapy for newly diagnosed malignant GBM, the overall survival time increased to more than 20 months [2]. Of particular note, the five-year survival rate increased from approximately 5 % to 10% [5]. Because of the EF-14 study, an increasing number of neuro-oncologists have started prescribing Optune for the treatment of GBM in addition to standard chemotherapy.

More GBM patients may be seen wearing this device on their heads and visiting neurologists of various subspecialties. First, the patient wearing Optune may present to neurologists with a variety of neurological issues just like patients without brain tumors. Second, the patients wearing

Optune may have complications from the tumor itself and treatment related complications such as seizure, headache, nausea, vomiting, focal or generalized weakness, fatigue, or stroke, for which they search for general neurology care because there may be no neuro-oncology service in their local area. Third, the patients may develop adverse effects from Optune.

The adverse effects of Optune are less compared to systemic chemotherapy. The major side effect is focal scalp irritation. Other uncommon side effects including headache, seizure, anxiety, depression, fatigue and insomnia, which might or might not be related to Optune since the trial found no statistical difference between the Optune trial group and the control group [2]. Health related quality of life is maintained [6]. For scalp irritation, the treatments include application of local steroid lotion or cream, and antibiotics ointment if needed. Patients are also allowed to wear Optune when they undergo a CT head study though are not allowed to wear it during a brain MRI study.

As neurologists, we need to be familiar with the concepts of the Optune treatment, the device itself and how to manage the potential side effects of the device when patients wearing Optune “Electric Cap” come to see us for management of their neurological issues.

## Abstract

Tumor treating fields (TTFields) is a new modality used for the treatment of glioblastoma. It is based on antineoplastic low-intensity electric fields induced by two pairs of electrode arrays placed on the patient's scalp. The layout of the arrays greatly impacts the intensity (dose) of TTFields in the pathology. The present study systematically characterizes the impact of array position on the TTFields distribution calculated in a realistic human head model using finite element methods. We investigate systematic rotations of arrays around a central craniocaudal axis of the head and identify optimal layouts for a large range of (nineteen) different frontoparietal tumor positions. In addition, we present comprehensive graphical representations and animations to support the users' understanding of TTFields. For most tumors, we identified two optimal array positions. These positions varied with the translation of the tumor in the anterior-posterior direction but not in the left-right direction. The two optimal directions were oriented approximately orthogonally and when combining two pairs of orthogonal arrays, equivalent to clinical TTFields therapy, we correspondingly found a single optimum position. In most cases, an oblique layout with the fields oriented at forty-five degrees to the sagittal plane was superior to the commonly used anterior-posterior and left-right combinations of arrays. The oblique configuration may be used as an effective and viable configuration for most frontoparietal tumors. Our results may be applied to assist clinical decision-making in various challenging situations associated with TTFields. This includes situations in which circumstances, such as therapy-induced skin rash, scar tissue or shunt therapy, etc., require layouts alternative to the prescribed. More accurate distributions should, however, be based on patient-specific models. Future work is needed to assess the robustness of the presented results towards variations in conductivity.

## Introduction

Glioblastoma multiforme (GBM) is a devastating brain cancer with an incidence of approximately 3–4/100,000 [1]. Standard therapy includes maximal safe resection of the tumor followed by radio-chemotherapy [2–8]. In addition, tumor treating fields (TTFields) are increasingly being used as a supplementary treatment modality for both recurrent and newly diagnosed GBM [9–12]. TTFields are low intensity ( $1\pm3$  V/m) intermediate frequency (200 kHz) alternating electrical fields, which inhibit tumor growth. Clinical trials with TTFields have demonstrated promising results [13–19]. For recurrent GBM, the technology performs as well as best physicians' choice chemotherapy but is associated with far less discomfort and adverse events [13]. For newly diagnosed GBM, TTFields increase the median overall survival by approximately five months when applied in addition to standard radio-chemotherapy [14,17,19–21].

TTFields are generated by two pairs of 3x3 electrode arrays placed on the scalp of the patient so that the fields induced by each pair are presumably orthogonal. Each pair of arrays is supplied by a portable and battery-powered current source carried by the patient. The sources are activated in sequence so when one source is active, the other is inactive and vice-versa. Each source has a repeated 50% square (on/off) duty-cycle of 2 s total duration, i.e. within one duty-cycle the source is active for 1 s, and then inactive for 1 s. During activation, each source induces a 200 kHz sinusoidal alternating field and the maximum peak-to-peak current delivered is 1.8A. The current level is controlled to maintain a skin temperature below 41°C. The therapeutic benefit depends on user compliance and the device "on-time" and the device should be active for at least 18 hours per day [22] ([https://www.optune.com/content/pdfs/Optune\\_PLOM\\_8.5x11.pdf](https://www.optune.com/content/pdfs/Optune_PLOM_8.5x11.pdf)).

The mechanism of action of TTFields is believed to relate mainly to direct physical interference with the mitotic process, such as septin and tubulin assembly and also direct migration of polarized particles in dividing cells [23–25]. Previous *in vitro* studies have established a significant dependency between the intensity of the induced field and the degree of tumor growth reduction [23,24]. The lower threshold of inhibition was determined to be 100 V/m while field intensities higher than 225 V/m induced tumor regression. Given this significant dose-response relationship, it is clear that the distribution of TTFields inside the head, brain, and tumor plays an important role for the expected treatment benefit for each patient. Therefore, methods to quantify this distribution are highly warranted, and recent studies have described various approaches to achieve this goal using finite element (FE) methods [26–36]. In a recent study, MRI data from a GBM patient were used to produce an accurate head FE model allowing for precise representation of the individual anatomy and dielectric property distribution. The approach was used to investigate the potential enhancement of TTFields using craniectomy and skull remodeling surgery to create paths for current flow directly into the tumor. In another study, a head model was constructed from MRI data of a healthy individual. The model was modified to incorporate virtual pathologies by post-processing of the head mesh [36] and used to identify general factors affecting the distribution of TTFields, such as tumor position, the type of surrounding tissue, and the presence of central necrosis in the tumor.

Despite the increasing focus on understanding the biophysics of TTFields, several questions remain unanswered. In this study, we will utilize a virtual lesion FE approach similar to the one described above to systematically investigate the impact of electrode position on the TTFields distribution and the average dose of TTFields experienced by tumors spanning a large range of the hemispheric regions. We will investigate the impact of systematic rotation of the transducer array pairs around a central craniocaudal axis of the head to investigate optimal configurations and transducer array layouts for various tumor locations. As a novel and significant finding, we

will show that an oblique array layout is superior to the standard left-right (LR) and anterior-posterior (AP) array layout for many tumor locations. Furthermore, our results will provide systematic and direct visual and quantitative information on the impact of electrode movement on the TTFields distribution. This information is highly important for clinicians and users who often have to adapt TTFields therapy and electrode layout to counter common challenges, such as therapy-induced skin rash beneath the electrodes. We hope to support users and clinicians to gain a better understanding of the TTFields therapy treatment and thereby aid treatment planning and optimize the clinical implementation of the technology.

## Methods

### Field calculations

We calculated the electric field distribution in a realistic model of a human head using a finite element (FE) approximation of the electric potential [26,27,33,35±38]. In general, the quantities defining a time-varying electromagnetic field are given by the complex Maxwell equations [39]. However, in biological tissues and at the low to intermediate frequency of TTFields ( $f = 200\text{kHz}$ ), the electromagnetic wavelength is much larger than the size of the head and the electric permittivity  $\epsilon$  is negligible compared to the real-valued electric conductivity  $\sigma$ , i.e.  $\frac{\omega\epsilon}{\sigma} \ll 1$ , where  $\omega = 2\pi f$  is the angular frequency [40]. This implies that the electromagnetic propagation effects and capacitive effects in the tissue are negligible, so the scalar electric potential  $\phi$  may be well approximated by the static Laplace equation  $\nabla \cdot (\sigma \nabla \phi) = 0$ , with appropriate boundary conditions at the electrodes and skin [26,31,40,41]. Thus, the complex impedance is treated as resistive (i.e. reactance is negligible) and currents flowing within the volume conductor are, therefore, mainly free (Ohmic) currents. The validity of this approximation for TTFields has further been established by Wenger *et al.*, 2015 [31], who showed that permittivity affects the intensity of the resulting field distribution in a realistic human head model by less than 2%. Similar observations were recently made by Lok *et al.*, 2017 [33]. Therefore, we have adopted the simpler electrostatic approximation in this study. We would like to note that, while this approach is valid for the estimation of the macroscopic field distribution in the head volume conductor, capacitive effects of the cell membranes have to be taken into account when modelling the penetration of the external current flow into tumor cells on the microscopic level [30,42]. However, the latter is not the topic of this study. The FE approximation of Laplace's equation was calculated using the SimNIBS software ([www.simnibs.org](http://www.simnibs.org)) [43]. Computations were based on the Galerkin method [44] and the residuals for the conjugate gradient solver were required to be  $<1\text{E}-9$ . Dirichlet boundary conditions were used with the electric potential was set to (arbitrarily chosen) fixed values at each set of electrode arrays [45,46]. The electric (vector) field was calculated as the numerical gradient of the electric potential and the current density (vector field) was computed from the electric field using Ohm's law. The potential difference of the electric field values and the current densities were linearly rescaled to ensure a total peak-to-peak amplitude for each array pair of 1.8 A, calculated as the (numerical) surface integral of the normal current density components over all triangular surface elements on the active electrode discs. This corresponds to the current level used for clinical TTFields therapy by the Optune® device. The "dose" of TTFields was calculated as the intensity ( $L^2$  norm) of the field vectors. We assumed the modeled current to be provided by two separate and sequentially active sources each connected to a pair of 3x3 transducer arrays (see below). The left and posterior arrays were defined to be sources in the simulations, while the right and anterior arrays were the corresponding sinks, respectively. However, as TTFields employ alternating fields, this choice is arbitrary and does not influence the results.

## Head model generation and positioning of tumors and arrays

A realistic head model was constructed from MRI data from a healthy individual (almi5 dataset available at [simnibs.org](http://simnibs.org)). The computational head mesh was initially segmented into skin, bone, cerebrospinal fluid (CSF), gray matter (GM) and white matter (WM). To ensure systematic positioning of tumors and electrode arrays, we defined a right-handed reference coordinate system in the model (Fig 1). We kindly refer the reader to Korshoej *et al.* (2017) for a full description of how this coordinate system was constructed [36]. In summary, a transversal plane was initially defined by conventional LR and AP positioning of the arrays. The left-right direction was defined as the x-axis, the AP direction as the y-axis, and the cranio-caudal direction normal to the xy-plane was defined as the z-axis.

After defining the coordinate system, nineteen spherical tumors were placed at systematically varying x, y and z coordinates to obtain a wide and clinically relevant range of cortical and sub-cortical tumor positions in the frontal, parietal, and occipital regions of the right hemisphere (Fig 1A). Tumor lesions were translated along the defined axes around a central position at the frontoparietal junction (corresponding to  $x = 40$  mm,  $y = 0$  mm,  $z = 0$  mm, see Fig 1). The exact tumor coordinates are stated in the caption of Fig 1 and the intersecting surfaces of all tumors are shown in Fig 1A and 1B along with corresponding x- and y-coordinate axes ( $z = 0$ ). Tumor lesions had external radii of 10 mm and inner core radii of 7 mm defining a core of central necrosis, as previously investigated by the Authors and by Miranda *et al.* [26,28,31].

Electrode arrays consisted of nine electrodes of 20 mm diameter arranged in a 3x3 array structure. The center-to-center distances between neighboring electrodes were 45 mm and 22 mm, respectively (Fig 1C). The transducer array configuration corresponded entirely to the Optune™ technology, which is used for clinical treatment. Transducer arrays were placed with their centers and longitudinal axes in the xy-plane. A pair of arrays was systematically rotated around the z-axis of the head model, i.e. in the xy-plane, from 0 to 180 degrees, thereby covering the entire circumference of the head (by symmetry). The rotation interval was 15 degrees,

**Fig 1. Visualization of coordinate system, tumor locations and electrode rotation.** A. Axial section in the xy-plane of the GM and WM surface of the head model with all tumor locations superimposed (radiological orientation). X- and y-axes are shown to illustrate tumor center coordinates in millimeters. The tumor position  $x = 40$  mm,  $y = 0$  mm, and  $z = 0$  mm is indicated by a solid arrow. All tumors were located in the electrode plane, i.e.  $z = 0$  mm and had the following x- and y-coordinates: X-translations (mm): (30, 0, 0), (32.5, 0, 0), (35, 0, 0), (37.5, 0, 0), (40, 0, 0), (42.5, 0, 0), (45, 0, 0), (47.5, 0, 0), (50, 0, 0). Y-translations (mm): (40, -40, 0), (40, -30, 0), (40, -25, 0), (40, -20, 0), (40, -10, 0), (40, 0, 0), (40, 10, 0), (40, 15, 0), (40, 20, 0), (40, 25, 0), (40, 30, 0). B. Same section as shown in panel A, but with illustrations of the tested electrode rotations in the xy-plane from 0 to 180 degrees at 15-degree intervals. C. Surface view of the head model with one electrode array pair in the AP position, i.e. 0 degrees. The x-, y-, and z- axes are shown along with a schematic illustration of the rotations path of the electrode arrays on the skin.

<https://doi.org/10.1371/journal.pone.0201957.g001>

corresponding to approximately 2 cm translations, giving a total of twelve different positions in the range of 180 degrees (Fig 1C). Calculations were performed for electrode positions at all tumor locations.

Isotropic conductivity estimates corresponded to previous *in vivo* measurements at comparable frequencies [47±49]. Anisotropic conductivity tensor estimates were obtained for GM and WM using diffusion MRI and a linear direct mapping technique [50]. This mapping linearly rescales the diffusion tensors by a common factor to obtain the conductivity tensors. The scaling factor is chosen so that the geometric mean of the eigenvalues of the conductivity tensors fits as well as possible in a least-squares sense to isotropic reference values (0.276 S/m for GM, and 0.126 S/m for WM). For the remaining tissue types, the following isotropic conductivities were used: Tumor 0.24 S/m, necrosis 1.00 S/m, skin 0.25 S/m; bone 0.010 S/m; and CSF 1.654 S/m. These values are based on average values obtained from *in vitro* and *in vivo* experiments at comparable frequencies [51±54]. Additional detailed information about the methods used in this study can be found in Korshoej *et al.*, 2016 [35], and 2017 [36].

## Results

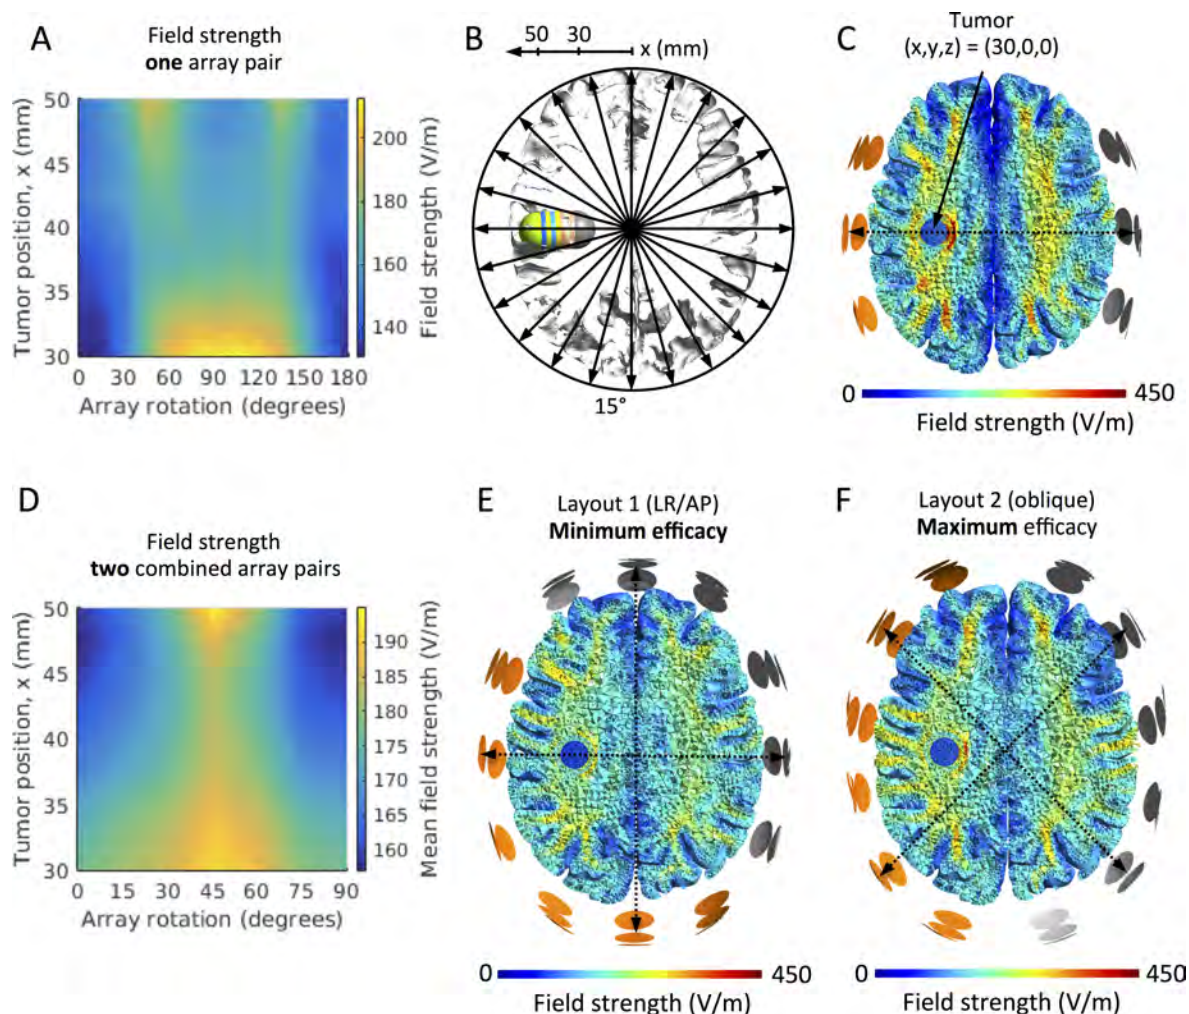

### Effect of array rotation

We investigated the impact of array rotation separately for tumors whose positions were varied along the x- and y-axes, respectively. Two-dimensional color maps were created to visualize the effect of rotation for different tumor positions systematically along each of the two axes. As previously described, TTFields therapy in its current form (Optune™) is applied using two sequentially active array pairs oriented orthogonally to each other. This is done to distribute the effect across cells dividing in different directions because the effect is higher when the field is applied in the direction of cell division [23]. To assess clinically relevant layout configurations, we, therefore, combined the results of all sets of array pairs oriented orthogonally to each other by calculating the average field induced by the two orthogonal pairs in the tumor tissue. This is equivalent to calculating the average peak field in the tumor over one duty cycle of TTFields for the given configuration and allows for direct efficacy assessment of orthogonal array configurations at different rotations around the head. The results are presented as both color maps as well as visual field maps showing the strength of the induced field in representative sections of the head model.

### Tumors translated in the left-right direction (x-axis)

The median field intensity in the tumor varied considerably with tumor location and array position (Fig 2). For all tumor locations, the direct AP array position at  $\theta = 0$  and 180 degrees induced the lowest median field strength ( $E = 131$  to  $148$  V/m). For tumors located in the cortical region, i.e. superficial to the sulcal fundi at  $x = 37.5$  to  $50$  mm, the field intensity showed two maxima at the oblique orientations of  $\theta = 45$  degrees ( $E = 165 \pm 193$  V/m) and  $\theta = 135$  degrees ( $E = 172 \pm 195$  V/m), respectively. This phenomenon is illustrated in Fig 2A. The field was slightly lower ( $E = 155 \pm 170$  V/m) for the LR array orientation,  $\theta = 90$  degrees. For tumors in the deeper subcortical regions ( $x = 30$  to  $35$  mm), the field showed a smooth curve with a single maximum at  $\theta = 90$  degrees ( $E = 179 \pm 209$  V/m). The field intensity at  $\theta = 90$  degrees increased for deeper tumor positions. Array positions at  $\theta = 45$  to  $\theta = 135$  degrees also induced high mean field intensities comparable to  $\theta = 90$  degrees. Fig 2C shows an example of the field distribution for the subcortical position  $x = 30$  mm. The supplementary material S1±S3 Videos show additional animations of the changing field distributions for all array rotations at representative tumor locations encompassing both cortical and subcortical positions, i.e.  $x = 30$  mm,  $x = 42.5$  mm, and  $x = 50$  mm, respectively.

**Fig 2. Effect of array rotation on field intensity for left-right tumor translations on the x-axis.** A. Color map of the median field intensity (V/m) in the tumors at varying x-positions (30 mm to 50 mm, *ordinate*) and varying rotations ( $\theta = 0$  to 180 degrees, *abscissa*) of a single pair of electrode arrays. Y- and z-coordinates were kept constantly at zero for all tumors, i.e. all tumors were in the center-to-center plane of the rotated array pairs. The figure shows field maxima at  $\theta = 45$  and 135 degrees, respectively, for all tumors between  $x = 35$  mm and 50 mm, while deeper seated tumors experienced high fields for all rotations between these values. B. Axial section of the GM and WM surfaces and the investigated tumors (x translations, i.e.  $x = 30$  to 50 mm,  $y = 0$  mm, and  $z = 0$  mm). Array rotations and tumor locations are indicated by the corresponding arrows and axis, respectively. C. Axial section (radiological convention) of the WM, GM and tumor volume ( $x = 30$  mm, position indicated by the solid arrow), showing an example of the topographical distribution of the field induced by TTFields (left-right array position,  $\theta = 90$  degrees). D. Color map comparable to panel A, but illustrating the mean field induced by two orthogonal array pairs. Tumor positions are indicated on the *ordinate* and the rotations of the posterior array on the *abscissa* ( $\theta = 0$  to 90 degrees). The figure shows a maximum mean field intensity at  $\theta = 45$  degrees equivalent to an oblique position of both pairs. The field distribution of this "optimal" layout is shown in panel F for the tumor position  $x = 30$  mm, while the distribution of the least effective layout ( $\theta = 0$  degrees) for the same tumor is shown in panel E.

<https://doi.org/10.1371/journal.pone.0201957.g002>

The average field strength induced by two orthogonal pairs of arrays was maximal at  $\theta = 45$  degrees, i.e. the combination of two oblique array pairs was superior to all other orthogonal combinations regardless of the tumor location along the x-axis (Fig 2D). In addition, S4 Video shows an animation of the sequence of field distributions induced by the optimal combination of orthogonal array pairs as the tumor is gradually translated from medial to lateral. As it is evident, the optimal array position is the oblique layout ( $\theta = 45$  degrees and  $\theta = 135$  degrees) for all tumors along the x-axis. The average field for the oblique layout was between  $E = 183$  V/m

and  $E = 195$  V/m depending on tumor position, and this corresponds to  $9 \pm 23\%$  enhancement compared to the least effective standard AP/LR layout at  $\theta = 0$  and  $90$  degrees. [Fig 2E and 2F](#) shows the topographical distribution of the average field for both the most effective array position  $\theta = 45/135$  degrees and the least effective  $\theta = 0/90$  degrees, respectively, at the tumor position ( $x = 30$  mm). Animations of the average field distributions for *combined* orthogonal arrays pairs are shown in the supplementary material [S4±S6 Videos](#) for all rotations and the same representative tumor locations,  $x = 30$  mm,  $x = 42.5$  mm and  $x = 50$  mm, as shown in [S1±S3 Videos](#).

### Tumors translated in the anterior-posterior direction, y-axis

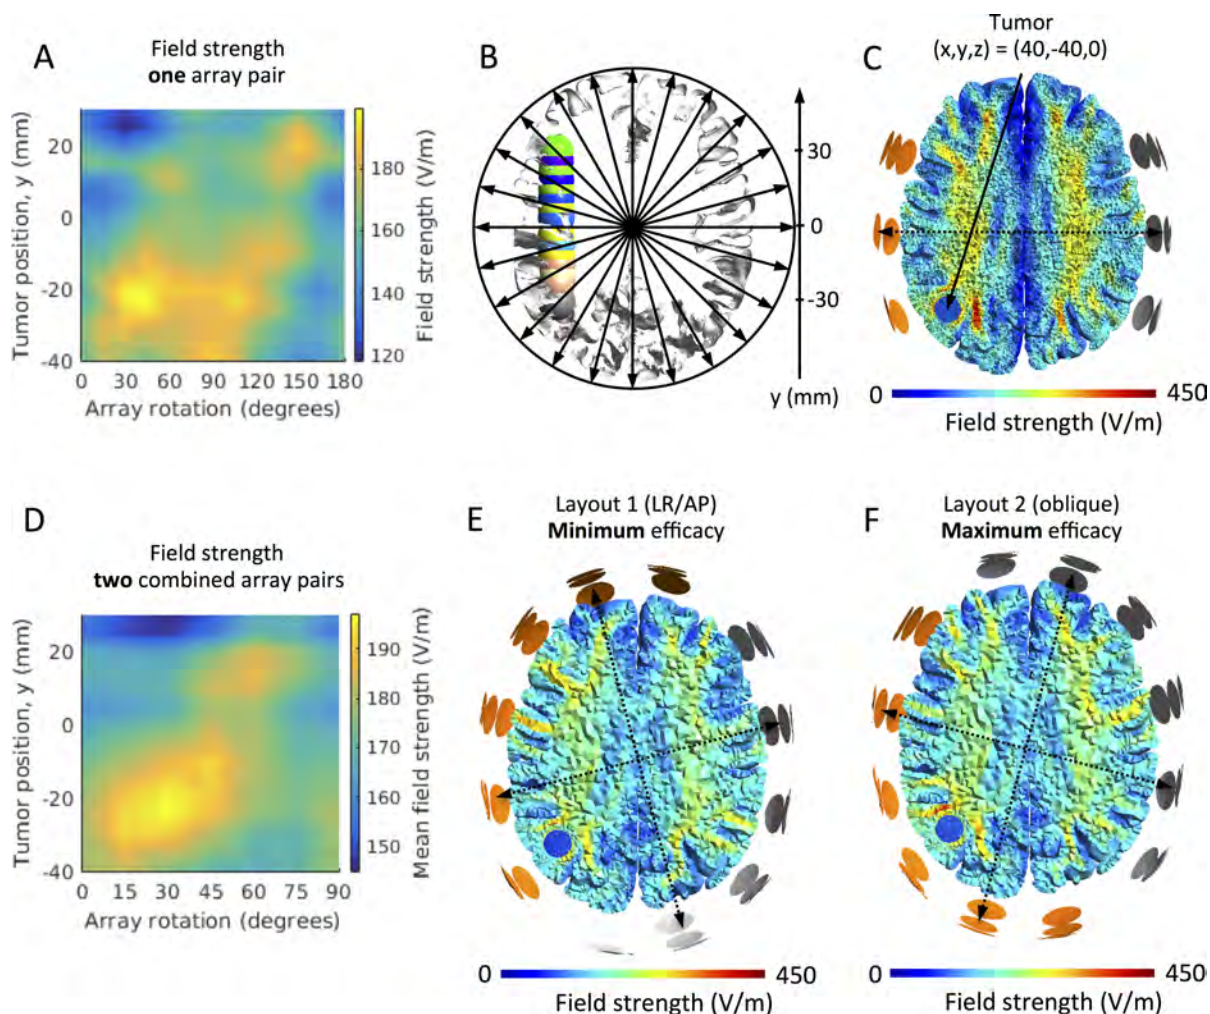

For most parietal and occipital tumors, i.e.  $y \leq 0$  mm, array positions between  $\theta = 15$  and  $\theta = 135$  degrees all tended to perform well and induced relatively high field values ([Fig 3](#)). For frontal tumors (i.e.  $y > 0$  mm) there was a tendency towards higher field values for array positions at  $\theta = 60$  degrees and higher. However, looking more closely at [Fig 3](#), we see that for most tumor positions in the anterior-posterior direction, there are two peaks in the plot of median field strength against different array rotations ([Fig 3A](#)), as it was also observed for cortical tumors translated in the left-right direction (see above). Correspondingly, the peak values also occurred at approximately orthogonal array positions. However, the array positions inducing peak field values varied with tumor location, as demonstrated in the oblique tendency of peak median field values in the color map. This observation is further illustrated in [Fig 3D](#), which shows the average median field strength for all combinations of two orthogonal pairs of electrode arrays. The figure shows, that *for every tumor position, an optimum position for each pair of orthogonal arrays exists. Furthermore, the optimum position is gradually rotated as the tumor is moved in the anterior-posterior direction.* This concept is further animated in the supplementary material [S8 Video](#), which shows the induced field distribution by the optimal array position for all tumors along the y-axis. As a general observation, for all the tumors the optimal layout was angled at approximately  $45$  degrees to the surface of the cortical region immediate overlying the tumor. Correspondingly, they were also oriented at approximately  $45$  degrees to the sulcal/gyral border in the vicinity of the tumor, as these were close to perpendicular to the brain surface. The field intensities induced by the optimum array layouts were generally  $10\%$  to  $17\%$  higher relative to the layout with the lowest efficacy. The oblique layout at  $\theta = 45$  degrees performed well for most tumor locations and better than the AP/LR layout ( $\theta = 0$  and  $90$  degrees) for all cases.

[Fig 3C](#) shows an example of the field distribution at the single array position ( $\theta = 90$  degrees) which induced maximum field intensity for a selected tumor at  $y = -40$  mm. Correspondingly, [Fig 3E and 3F](#) show examples of the orthogonal combination of electrode layouts with the highest ( $E = 183$  V/m) and lowest mean field intensity ( $E = 167$  V/m) for the same tumor location, respectively. The supplementary material [S9±S12 Videos](#), shows animations of the field distributions induced by single rotating array pairs for tumor locations spanning a large ( $7$  cm) anterior-posterior range, i.e.  $y = -40$  mm,  $y = -40$  mm,  $y = -20$  mm,  $y = 20$  mm, and  $y = 30$  mm. The corresponding distributions of *combined* orthogonal arrays pairs (mean field intensity) are shown in [S13±S16 Videos](#) for the same tumor positions, respectively.

### Discussion

In this study, we used realistic head models and finite element calculations to compute the distribution of TTFields for a large number of transducer array layouts and tumor positions. Specifically, we have investigated the impact of systematic rotation of a pair of transducer arrays around a central craniocaudal axis of the head on the dose of TTFields in nineteen

**Fig 3. Effect of array rotation on field intensity for anterior-posterior tumor translations, y-axis.** A. Color map of the median field intensity (V/m) in tumors at varying  $y$ -positions (-40 mm to 30 mm, *ordinate*) and varying rotations ( $\theta = 0$  to 180 degrees, *abscissa*) of a single pair of electrode arrays. X- and z-coordinates were kept constant at  $x = 40$  mm and  $z = 0$  mm, respectively, for all tumors, i.e. all tumors were in the center-to-center plane of the rotated array pairs. The figure shows field maxima at two separate rotations for the most tumors. The two maxima were separated by approximately 90 degrees. B. Axial section of the GM and WM surfaces and the investigated tumors ( $y$  translations, i.e.  $x = 40$  mm,  $y = -40$  to 30 mm, and  $z = 0$  mm). Array rotations and tumor locations are indicated by the corresponding arrows and the axis, respectively. C. Axial section (radiological convention) of the WM, GM and tumor volume ( $y = -40$  mm, position indicated with a solid arrow), showing an example of the topographical distribution of the field induced by TTFields (left-right array position,  $\theta = 90$  degrees). D. Color map comparable to panel A, but illustrating the mean field induced by two orthogonal array pairs. Tumor positions are indicated on the *ordinate* and the rotations of the posterior array on the *abscissa* ( $\theta = 0$  to 90 degrees). The figure shows a single maximum of the mean field intensity at varying rotations depending on the tumor of interest. The field distribution of the "optimal" layout is shown in panel F for the tumor position  $y = -40$  mm, while the distribution of the least effective layout ( $\theta = 0$  degrees) for the same tumor is shown in panel E.

<https://doi.org/10.1371/journal.pone.0201957.g003>

systematically varied tumor positions. We have identified optimum array positions for each tumor position and presented elaborate animations and graphical representations to provide users with a more intuitive understanding of the effect and distribution of TTFields and how this depends on the tumor and electrode array position.

As general observations, we found that varying the array layout produced markedly different field distributions and that the array position had a great impact (up to 23%) on the median field intensity observed in the tumor region for all studied tumor positions. In particular,

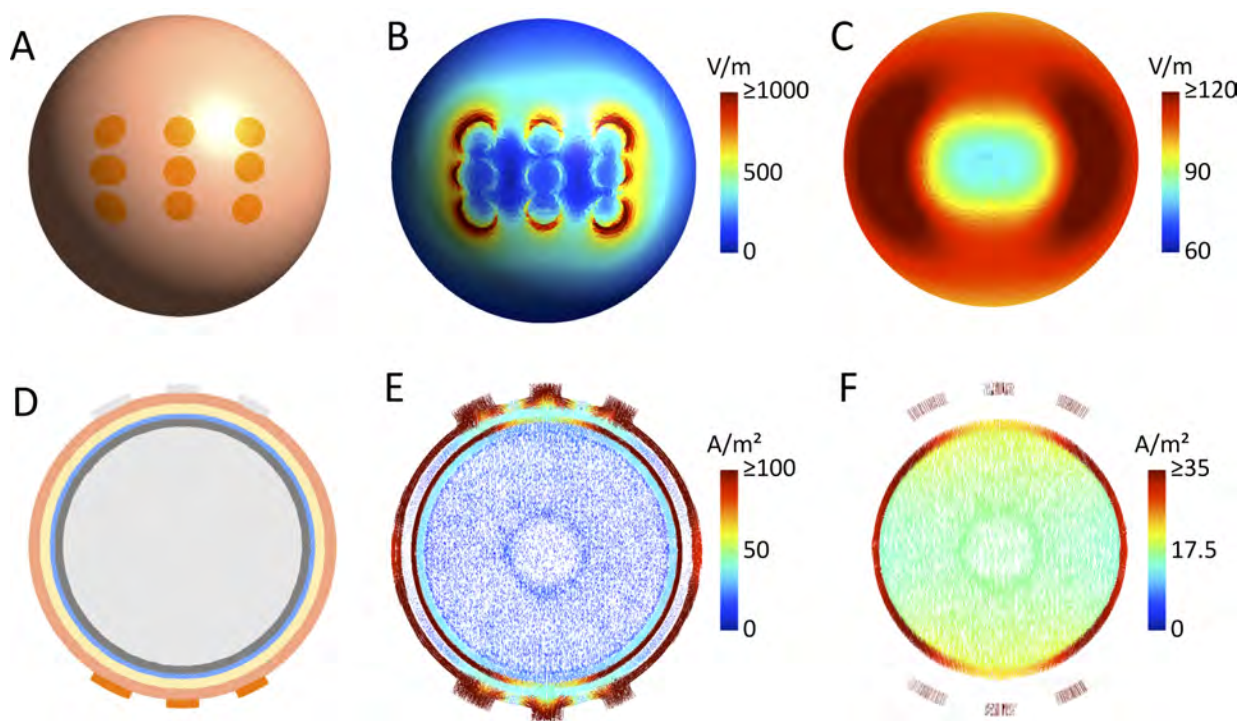

when varying the tumor from left to right (Fig 2A), there was a bimodal dependency between the field intensity in the tumor and the array position, meaning that the field dose peaked at two separate (optimal) array positions. This result was observed for most superficial tumor positions in the cortical regions. In addition, the two optimal array positions were close to orthogonal for most tumors, i.e. positioned at ninety-degree intervals to each other. In the deeper subcortical regions, we observed a single optimum array position at which the field was maximal ( $\theta = 90$  degrees), however, high field intensities were observed for a wide range (45 to 135 degrees) of electrode positions, and the optimum combination of two orthogonal field pairs had a single peak at  $\theta = 45$  degrees as observed for the superficial tumors on the x-axis.

When varying the tumor position in the anterior-posterior direction, we observed a significant dependency between the optimum array configuration and the tumor position. Specifically, the optimum position of the orthogonal pair of arrays was gradually shifted clock-wise as the tumor was moved from posterior to anterior positions (viewed in radiological convention). However, array positions between  $\theta = 15$  and 135 degrees were all relatively effective for most parietooccipital tumors, while rotations of  $\theta = 135$  degrees or higher were generally more effective for frontal tumor locations.

Due to the size of the electrode arrays, superficial tumors in our simulations were close to one of the outer electrode columns of an array for the oblique array orientations. It is interesting to note that the fields in the more superficial brain regions tend to be stronger underneath the outer electrodes than the central electrode of an array (see, e.g. S3 Video). This resembles the well-known edge effect for large pad electrodes used in transcranial electric brain stimulation [55], due to which the field is higher underneath the edges compared to the center of these electrode pads. Here, given that all electrodes of a TTFields electrode array are connected to the same channel and thus have the same electric potential, the same effect occurs and causes an unequal distribution of the current strength across the electrodes, with the outer electrodes tending to induce stronger currents into the underlying skin area (Fig 4 shows this exemplarily for a spherical head model). This effect is influenced by the local tissue conductivities underneath the electrodes (e.g., thin vs. thick skull) and thus varies across array orientations. However, the simulation results indicate that it is observed for the majority of orientations. As a consequence, when employing orthogonal pairs of arrays at an oblique orientation, superficial tumors will be close to an outer electrode column of one of the arrays for each of the two pairs, resulting in high median field strength. This explains the superiority of the 45° layout compared to the standard LR and AP electrode montages for the superficial tumor positions when varying the position from left to right. This effect is further increased by the generally low field intensity caused by the AP electrode array pair (0 and 180 degrees in Fig 2A; please refer to Korshoej *et al.* (2017) for a discussion of the reasons underlying the differences between LR and AP). The enhanced field intensities underneath the outer electrode columns also explain the gradual shift of the optimal array orientation when varying the tumor position from posterior to anterior. This is exemplified by the superficial tumor location  $x = 50$  mm ( $y = 0$  mm and  $z = 0$  mm), which experienced the strongest fields at 45 degrees and 135 degrees, when the tumor was closest to the anterior and posterior electrode columns, respectively, S3 Video. The reduction of field intensity at angles between the two maxima (minimum at the left/right array position, Fig 2A) may also be explained in part by the edge effect because lower currents are induced underneath the central electrode. A likely contributing factor, however, is the fact that increasing amounts of current are shunted through the sulci and thus pass the tumor when the field is oriented increasingly in parallel with the sulci, i.e. close to the LR position.

The LR and AP configuration is a commonly employed layout for a wide range of tumors *In this study, we find that the vast majority of the investigated cases would benefit more from the oblique configuration (45 degrees to the sagittal plane) than from the LR/AP array configuration,*

**Fig 4. "Edge" effects for 3x3 electrode arrays.** A. One of the two electrode arrays seen from above. B. Electric field distribution on the skin surface. The higher field strengths at the outer edges of the electrode array are clearly visible. C. Electric field distribution on the GM surface. The distribution is smoother than on the skin surface, but the lower field strengths underneath the array center are still clearly observed. D. Cut through the spherical head model. It consists of a central WM sphere ( $r = 7.5$  cm), surrounded by GM (outer  $r = 8.0$  cm), CSF (outer  $r = 8.3$  cm), skull (outer  $r = 8.9$  cm) and skin (outer  $r = 9.5$  cm). The same tissue conductivities as for the head model were used, see [Methods](#). GM and WM were modelled as isotropic with  $\sigma_{GM} = 0.276$  S/m and  $\sigma_{WM} = 0.126$  S/m. E. Current flow in the plane shown in D. The lower current densities in the skin and CSF layers underneath the central electrode are clearly observable (the different arrow densities in the sphere center are an artefact of the meshing process and do not influence the results). F. Current flow in GM and WM in the same plane. The lower current densities in the GM layer underneath the central electrode are clearly visible.

<https://doi.org/10.1371/journal.pone.0201957.g004>

although even further optimization may be performed in accordance with the above results. Specifically, the field was maximized when the neighboring arrays were orthogonal and placed such that their outermost columns of electrodes were close to the tumor. We found that each tumor position was associated with a single optimum position of two orthogonal array pairs, at which the induced field was highest. From a treatment efficacy point of view, the ninety-degree relationship between optimal array positions (bimodality, Figs 2A and 3A) is highly convenient. This is because clinical TTFields therapy is performed with two orthogonal pairs of arrays in order to target cells with a different (random) direction of mitosis and distribute the tumor-inhibiting effect across larger regions of the pathology [23].

In general, our observations support the notion that the dose of TTFields, and therefore expectedly also the therapeutic efficacy, depends significantly on the positioning of transducer arrays on the scalp. Under normal circumstances, a personalized layout is produced for each patient prior to treatment initiation, using the software NovoTAL™ (Novocure, Ltd.). Very often, however, clinicians are faced with the challenge of having to deviate from the optimum layout due to various circumstances, such as scar tissue, use of metallic bone-fixation implants following surgery, or shunt therapy, etc. In addition, patients are recommended to move the arrays by approximately 2 cm when they are changed every  $3 \pm 4$  days. This is done to minimize the risk of skin rash beneath the electrodes, which is a commonly observed side effect of TTFields therapy. Our results may be used to support clinicians and users in deciding optimal

array layouts for patients undergoing therapy, when facing challenges as described above. Of the tumors investigated, many would be treated with the LR and AP array layouts. This layout is produced from FE calculations of the field distribution, based on field head models adapted to the individual head and tumor morphometrics comparable to the approach used here. Our results suggest that some patients may in fact benefit more from the oblique array layout or layouts adapted in accordance with the above. In any case, the results presented provide viable alternative layouts for a wide range of tumors.

## Limitations and future perspectives

It is important to highlight that the investigated model reflects a limited, but comprehensive variety of scenarios specific for the individual case. Although a large number of tumor and array positions were investigated, personalized modeling experiments should ideally be conducted to account for the complex individual variations in anatomy and (as far as possible) tissue conductivities, including the shape and size of the head and tumor, observed in real tumor patients. Personalized approaches may account more accurately for the expected treatment efficacy and support more precise, safe and efficacious treatment planning. In addition, personalized approaches based on new and representative MRI data would enable a better and timelier characterization of the TTFields distribution at the moment of interest. Thereby the model would better account for changes, e.g. in tumor size or tissue composition, which may occur during the course of TTFields treatment as a result of disease development or therapy. Recently, the authors published an example of an individualized approach to TTFields modeling.

It should also be emphasized that the ohmic conductivity estimates used in the model markedly influence the results of the field calculations (see [Methods](#)). Recent studies by Wenger *et al.*, 2015 [31], and Lok *et al.*, 2017 [33], assessed the sensitivity of TTFields FEM models, such as the one employed in this study, towards dielectric property variations. They conclude that the conductivity variations significantly influence the distribution of TTFields, while permittivity variations only play an insignificant role. In this study, we thus neglected the influence of permittivity and have employed common conductivity values taken from the literature. However, it should be emphasized that the biological tissue conductivities have not been firmly established at 200 kHz, so that the resulting uncertainty might impact the generalizability of our results. However, since the field changes observed with changing tumor and electrode position were primarily associated with relative differences in conductivity between brain tissue, tumor tissue, and CSF [36], the observations reported will likely hold for a range of conductivity variations, as long as the differences in conductivity are in the same direction, i.e. the conductivity of CSF is higher than the conductivity of tumor, and the conductivity of tumor is higher than the conductivity of brain tissue. Although the absolute field values will change with varying conductivities, we expect that our main findings and conclusions will hold for a wide range of scenarios.

In addition to field intensity, future models should ideally also incorporate information about exposure time and the amount of non-orthogonality (i.e., directional correlation) of the electric fields that are induced by the two electrode array pairs in the tumor. The latter aspect relates to the finding that the effects of TTFields on a dividing cancer cell are enhanced when the field is aligned with the direction of cell division. Given that this direction varies randomly across tumor cells, treatment efficacy seems to be improved when two or more oblique fields rather than a single field direction are used [23]. Also, future models should incorporate better segmentations of the pathology to obtain representative field estimates in the true regions of interest. Finally, it is important to highlight that future consideration should also be given to validating the simulation results by means of direct TTFields measurements in vivo.

## Conclusion

We present novel findings, describing the impact of systematic positional variation of TTFields electrode arrays on a human head for a large number of tumor locations in the brain. For most superficial tumor positions, we found that there were two optimal array positions, at which the median field intensity was highest. These varied systematically (i.e. clockwise rotation), as the tumor position was translated from posterior to anterior, while it was unaffected by left-right tumor translations. In addition, the two optimal layouts were oriented approximately orthogonally to each other. Correspondingly, we found that there was a single optimal layout of combined orthogonal array pairs, at which the median TTFields dose was highest. The optimum position also varied systematically in accordance with the above and in general, the optimum arrays were oriented at 45 degrees to the surface of the brain immediately overlying the tumor. We also found that one particular layout was more effective for most tumor locations compared to the standard LR and AP combination of array pairs. This layout was composed of two orthogonal and oblique array positions both oriented at 45 degrees to the mid-sagittal plane. The presented results may generally guide layout configuration in clinical cases where deviations from the suggested NovoTAL layout are required, e.g. due to therapy-induced skin rash, etc. Furthermore, the oblique configuration may potentially be used as an effective, alternative layout for most tumors although further optimization may be expected by direct comparison with tumor representative locations. In addition, our results present extensive animations and graphical representations, to illustrate the impact of tumor and electrode positions on the distribution of TTFields. Our results will hopefully improve users' understanding of TTFields and support clinical decisions on TTFields therapy.

The modeling approach used in this study is widely adopted. However, it must be noted that variations in tissue conductivities and head morphology are likely to affect the results. Further studies are required to estimate the robustness and sensitivity of the suggested conclusions towards these variations. Also, accurate field estimation should ideally be computed from patient-specific head models, which accurately represent the anatomy and tissue conductivity of the given individual.

Regarding the randomization, women were randomized by a web-based system (<http://www.randomization.com>) using random blocks of 2, 4, and 6 to receive the pessary or no pessary. Randomization was stratified by cervical length, and separate randomization sequences were created by an independent statistician. However, there was an error in the article. The randomization strata were less than 20 mm and equal or greater than 20 mm to equal or less than 25 mm, not equal or less than 20 mm and greater than 20 mm to equal or less than 25 mm as stated. Using the erroneous cutoff would lead to imbalance between the groups, as Thornton suggested. However, with the correct cutoff, no imbalance was noticed, with 125 women with a cervical length less than 20 mm and 25 women with a cervical length equal or greater than 20 mm to equal or less than 25 mm in each group. The number of women with a cervical length equal or less than 20 mm in Table 1 was correct, as equal or less than 20 mm was the cutoff used for vaginal progesterone therapy, as recommended by guidelines.<sup>2</sup> The article has been corrected online and we apologize for any confusion this may have caused.

Regarding the Kaplan-Meier curves, the numbers of women at risk, reported in Figure 2, were the total number of randomized women minus the number of women who already delivered, regardless of whether they had iatrogenic or spontaneous preterm birth. Therefore, the numbers of women at risk are the same for both curves.

The benefits of the pessary shown in our trial could be explained by the high treatment adherence compared with other trials. There are several ongoing trials evaluating the efficacy of cervical pessary in prevention of preterm birth, and there are plans for an individual patient data meta-analysis that will include our data. The meta-analysis will update prior reviews<sup>3,4</sup> and hopefully will clarify the effect of cervical pessary in prevention of preterm birth.

## Quality of Life in Patients With Glioblastoma Treated With Tumor-Treating Fields

**To the Editor** In a multisite, randomized, phase 3, clinical trial, Dr Stupp and colleagues<sup>1</sup> demonstrated a modest benefit for patients newly diagnosed with glioblastoma treated with tumor-treating fields (TTFields) and temozolomide vs temozolomide alone in progression-free survival (7.1 months for TTFields plus temozolomide vs 4 months for temozolomide alone) and overall survival (20.9 months for TTFields plus temozolomide vs 16 months for temozolomide alone). The authors should justify the current cost of the device (\$20 000 per month) and also discuss the effect on quality of life for both the patients (shaving their head) and family when patients wear the TTFields device 18 hours a day.

Cognitive (Mini-Mental State Examination) and functional (Karnofsky performance score) metrics were included in their analysis, but the use of standardized, health-related quality-of-life scores (such as the European Organisation for Research and Treatment of Cancer quality-of-life questionnaire and its brain-specific module) were not mentioned. Tumor-treating fields plus temozolomide compared with temozolomide alone showed no significant differences in time to a sustained 6-point decline in the Mini-Mental State Examination score.<sup>1</sup> Standardized health-related quality-of-life scores take into account emotional, social, and role functioning.<sup>2</sup> An interim analysis conducted on the first 315 randomized patients did not show significant differences for any of the functional scales on either questionnaire in either treatment group.<sup>2</sup> A larger analysis incorporating 92% of the patients noted that 42% of patients had not completed the questionnaires at the 1-year follow-up.<sup>3</sup> The physical and emotional burden of shaving one's head while wearing the device 18 hours a day (including while sleeping) cannot be underestimated for both patient and family members. In fact, it is the partner, friend, or family member who must change the adhesives, administer scalp care, and adjust the TTFields device when it malfunctions, even in the middle of the night.

Other trials, perhaps with less significant psychiatric implications, may be better suited for patients with newly diagnosed glioblastoma. For example, a phase 3 trial (CeTeg/NOA-09) showed that the combination of lomustine and temozolomide significantly improved median overall survival (37.9 months with lomustine, temozolomide, and radiotherapy vs 31.4 months with temozolomide and radiotherapy alone) in patients with the O<sup>6</sup>-methylguanine-DNA methyltransferase (MGMT) promoter.<sup>4</sup>

In sum, although TTFields plus temozolomide provides an interesting and innovative treatment for newly diagnosed glioblastoma, a better understanding of the effect on patient and family quality of life needs to be assessed, especially to justify TTFields's increased economic and emotional burden.

**In Reply** Our randomized trial demonstrated a consistent improvement in both progression-free and overall survival when TTFields was included in first-line therapy for glioblastoma. The hazard ratio for death was 0.63, translating into an improvement in the 2-year survival rate from 31% to 43%. For comparison, the addition of temozolomide to radiotherapy compared with radiotherapy alone also resulted in a hazard ratio of 0.63, with a 2-year survival rate increasing from 10% to 27%.<sup>1</sup> One may consider the improvements modest, yet these are the most effective proven treatments available.

Cancer treatments, be it surgery, irradiation, chemotherapy, or TTFields, all have their inherent toxicities and inconveniences. The results of the health-related quality-of-life analyses that Dr Kwan and colleagues requested have recently been published in detail.<sup>2</sup> The main adverse effect of TTFields was skin reactions (mostly mild) at the site of electrode placement. We hypothesized that wearing the device could either decrease health-related quality of life through its burden on the patient, including physical impairment or a decreased social or role functioning due to the visibility of the device, or increase it through an improved feeling of well-being related to active participation of both the patient and the caregiver in the fight against the disease. Instead, no statistically significant differences in health-related quality of life between baseline and 12 months were observed between groups, except for itchy skin in the TTFields group. Health-related quality-of-life scores were maintained for a longer period in the TTFields group due to the longer time to tumor progression and survival. Missing longitudinal quality-of-life data are an inherent problem of many studies as is overrepresentation of patients with favorable prognostic factors. However, our mixed-model analyses, accounting for missing data, confirmed the results found in the mean change from baseline analyses.

Kwan and colleagues point out that there may be other treatments that could confer a benefit in outcome. We embrace any future advances made in the treatment of patients with malignant glioma. The TTFields treatment has no overlapping toxicities and thus could be combined with any other

promising therapy; TTFields treatment is an important step toward improvement in survival, but further research is needed to ultimately cure patients with glioblastoma.

## The National Resident Matching Program and Competition for Employment

**To the Editor** Dr Curtin and Ms Signer<sup>1</sup> advocated for the policies of the National Resident Matching Program (NRMP) to maintain “a fair, efficient, and reliable matching process.” However, we believe this article minimizes the inherent inequity of the NRMP binding match commitment, which requires medical students to enter the Match contractually obligated to an employment agreement they have never seen. Matched applicants are then not allowed any negotiation of the employment agreement that they were bound to sign. Rigorous enforcement of these contracts are justified by Curtin and Signer to ensure the “integrity” of the process, which is the only means of securing residency positions in the United States.

The contractual obligation of resident physicians to the NRMP fundamentally violates antitrust laws by undermining competition in recruitment and hiring, thereby lessening employment choice and compensation. In the face of a court challenge to the NRMP, the process has been protected from legal scrutiny by Congress. This was accomplished through an exemption of the NRMP in an amendment to the unrelated Pension Fund Equity Act of 2004. The amendment, which had not undergone hearings before appropriate committees, retroactively and permanently exempted graduate medical education programs from antitrust law.

We agree that the NRMP is efficient and effective; in fact, the 2012 Nobel Prize in Economics was awarded for the algorithm on which the NRMP is based.<sup>2</sup> However, the Congressional exemption of the NRMP from antitrust laws and the secretive means by which it was enacted were not proper. The amendment to the Pension Fund Equity Act of 2004 was not procompetitive, as it prevents fair negotiations at the heart of all employment agreements.<sup>3</sup>

# Dosimetric Impact of a Tumor Treating Fields Device for Glioblastoma Patients Undergoing Simultaneous Radiation Therapy

**Purpose:** A recent randomized phase III clinical trial in patients with glioblastoma demonstrated the efficacy of tumor treating fields (TTFields), in which alternating electric fields are applied via transducer arrays to a patient's scalp. This treatment, when added to standard of care therapy, was shown to increase overall survival from 16 to 20.9 months. These results have generated significant interest in incorporating the use of TTFields during postoperative concurrent chemoradiation. However, the dosimetric impact of high-density electrodes on the scalp, within the radiation field, is unknown.

**Methods:** The dosimetric impact of TTFields electrodes in the radiation field was quantified in two ways: (1) dose calculated in a treatment planning system and (2) physical measurements of surface and deep doses. In the dose calculation comparison, a volumetric-modulated-arc-therapy (VMAT) radiation plan was developed on a CT scan without electrodes and then recalculated with electrodes. For physical measurements, the surface dose underneath TTFields electrodes were measured using a parallel plate ionization chamber and compared to measurements without electrodes for various incident beam angles and for 12 VMAT arc deliveries. Deep dose measurements were conducted for five VMAT plans using Scandidos Delta4 diode array: measured doses on two orthogonal diode arrays were compared.

**Results:** In the treatment planning system, the presence of the TTFields device caused mean reduction of PTV dose of 0.5–1%, and a mean increase in scalp dose of 0.5–1 Gy. Physical measurement showed increases of surface dose directly underneath by 30–110% for open fields with varying beam angles and by 70–160% for VMAT deliveries. Deep dose measurement by diode array showed dose decrease of 1–2% in most areas shadowed by the electrodes (max decrease 2.54%).

**Conclusion:** The skin dose in patients being treated with cranial irradiation for glioblastoma may increase substantially (130–260%) with the addition of concurrent TTFields electrodes on the scalp. However, the impact of dose attenuation by the electrodes on deep dose during VMAT treatment is of much smaller, but measurable, magnitude (1–2%). Clinical trials exploring concurrent TTFields with cranial irradiation for glioblastoma may utilize scalp-sparing techniques to mitigate any potential increase in skin toxicity.

**Keywords:** glioblastoma multiforme, radiation therapy, tumor-treating fields, dose calculation, skin dose

## INTRODUCTION

Glioblastoma remains the most common primary brain malignancy, with more than 13,000 patients diagnosed in 2017 in the United States (1). The median overall survival for patients diagnosed with glioblastoma is dismal, ranging from 15 to 16 months in prospective randomized studies performed in the first decade of this century (2, 3). This median survival resulted from the introduction of temozolomide, an alkylating chemotherapy given concurrently and adjuvantly with radiation therapy (RT) after maximal safe neurosurgical resection; prior to the use of temozolomide, clinical trials routinely demonstrated a median survival of approximately 12 months. The poor prognosis of this disease has motivated clinical trials of radiation dose escalation, novel drug therapies, and other unconventional approaches. The most successful of these approaches has been the introduction of tumor treating fields (TTFields), in which alternating electric fields are applied *via* transducer arrays to a patient's scalp. This technique has been demonstrated to have anti-mitotic activity in tumor cells and showed promise in patients with recurrent disease (4–7). The technique was applied in patients immediately after the conclusion of adjuvant chemoradiation in a randomized phase III study, which showed increased overall survival from 16 to 20.9 months (8).

This remarkable improvement has generated significant interest in the use of TTFields earlier in the treatment course—that is, during the course of postoperative concurrent chemoradiation—in an attempt to evaluate the potential synergistic effect of multimodality therapy. However, the delivery of TTFields requires the placement of metallic transducer electrodes of high density onto the scalp of patients, directly into the radiation field. The dosimetric impact of an array of electrodes placed directly in the radiation field is not precisely known, and without this knowledge, estimation of the potential for toxicity with combined therapy is more difficult.

High-density objects on the surface of the patients receiving RT can have non-negligible and competing effects on the dose distribution in the patient's body. On the one hand, the metal acts like additional buildup material, generating additional electrons *via* the photoelectric effect or Compton process. Clinically, this could translate into increased skin dose below the TTFields electrodes.

On the other hand, high-density materials can also act as an attenuator, reducing the dose to deeper tissues while simultaneously hardening the radiation beam *via* preferential attenuation of low energy photons. Clinically, this may impact the percentage depth dose curve and potentially decrease the target volume dose.

The present work is thus motivated by these physical principles, as well as the improvement in clinical outcomes with TTFields. We investigate both the buildup and attenuation/filtering effects of the TTFields electrode array on a scalp phantom, using both advanced dose calculation algorithms in the treatment planning environment and physical measurements of electrodes impact on surface and deep dose. We hypothesize that quantification of the dosimetric impact of the electrodes may facilitate the development and execution of clinical trials evaluating combination

chemoradiation and TTFields for patients with newly diagnosed glioblastoma.

## MATERIALS AND METHODS

### Planning Study

The planning study was done on the Anderson RANDO phantom. A CT scan of the phantom was acquired, with and without the TTFields device. Target volumes and organs-at-risk contours from 10 patients previously treated for glioblastoma were used to generate clinical contours on the RANDO phantom. The target and normal tissues from these cases were transferred to the RANDO phantom and then modified by a radiation oncologist to be as realistic as possible.

These phantom patients were each planned using volumetric-modulated-arc-therapy (VMAT) in Varian Eclipse® treatment planning system. Planning techniques were duplicated from the original clinical treatment plans for the number of arcs and the arc angle ranges. The metal electrodes from the TTFields treatment devices were contoured on the CT scans and assigned a fixed density equal to the highest allowable value in each treatment planning system, which is around the density of aluminum, to reduce the impact from metal artifacts on dose calculation and maintain consistent electrode positions between different phantom plans. The dose calculation algorithm was set to AcurosXB v11 for its higher accuracy on calculating dose around high-Z materials (9).

All treatment plans were optimized on the scan without electrodes, which is how patients would be scanned and simulated during an actual clinical treatment plan design process. The prescription dose for all plans in this study was 60 in 2 Gy per fraction. Normal tissue objectives followed RTOG 0825 protocol: brainstem Dmax < 60 Gy, optical chiasm Dmax < 56 Gy, optical nerves Dmax < 55 Gy, lenses Dmax < 7 Gy, scalp Dmean < 20 Gy, scalp D20cc < 40 Gy, and scalp D10cc < 50 Gy. Plans were normalized so that the 100% prescription line covers 95% of the PTV volume. While keeping all plan parameters the same, the dose distribution was then recalculated on the phantom with the metal electrodes to assess the impact from the electrodes on key dosimetric parameters.

Paired comparison between treatment plans with and without electrodes were performed first for PTV coverage using percentage of PTV receiving at least Rx dose. The scalp dose was also compared to assess the dose buildup effect caused by the presence of metal object close to the skin. All comparisons were tested using Wilcoxon signed rank test to determine statistical significance.

### Physical Measurements

To further evaluate the impact of skin and deep doses from the presence of the TTFields electrodes, physical measurements were also conducted.

Surface dose changes were measured using a parallel plate ionization chamber (10). The chamber was placed in the solid water phantom with 10 cm backscatter, and the surface of the chamber was matched with the surface of the phantom. To protect the chamber, a 0.87 mm acrylic cap was placed on the front window of the parallel plate chamber, making the effective point of measurement at 1 mm depth in tissue equivalent media. The TTFields electrodes

were then placed on top of the acrylic cap to mimic placement on a patient's scalp. The radius of active volume of the chamber was much less than the radius of the electrodes; therefore, the partial volume effect as a result of the electrode partially blocking the chamber was minimized. All measurements were first performed with 10 cm × 10 cm field size at 100 cm SSD. Charges were collected with and without TTFields electrodes for incident beam angles at  $-85^\circ$ ,  $-75^\circ$ ,  $60^\circ$ ,  $30^\circ$ ,  $0^\circ$ ,  $30^\circ$ ,  $60^\circ$ ,  $75^\circ$ , and  $85^\circ$  relative to the axis perpendicular to the surface of the chamber. In addition, surface doses with and without TTFields electrodes were also compared using actual VMAT plans delivered to a 20 cm × 20 cm × 20 cm solid water phantom. Surface doses for VMAT plans were measured with

above-mentioned parallel plate chambers mounted with a special inset on the surface of the solid water phantom, with the chamber's measurement window flush to the solid water phantom surface to mimic the actual scatter condition from the patient. Other *in vivo* dosimetry devices such as thermal luminescence dosimeter (TLD) or optically stimulated luminescence dosimeter (OSLD) were not chosen because of unavailability (TLD) and larger measurement uncertainty ( $\sim 5\%$  for OSLD).

In addition to surface dose, deep dose measurements were conducted using Delta4 device (Scandidos AB, Sweden) that are currently used clinically to verify all VMAT treatment in our clinic (11). As shown in **Figure 1**, this device has two planes of diode arrays that measures dose distribution within a cylindrical phantom. To mimic clinical treatment with TTFields, the electrodes were placed directly onto the surface of the phantom where beams would enter. The measurements were compared with and without electrodes. Histograms and mean dose deviation were used to assess deep dose differences caused by the TTFields electrodes.

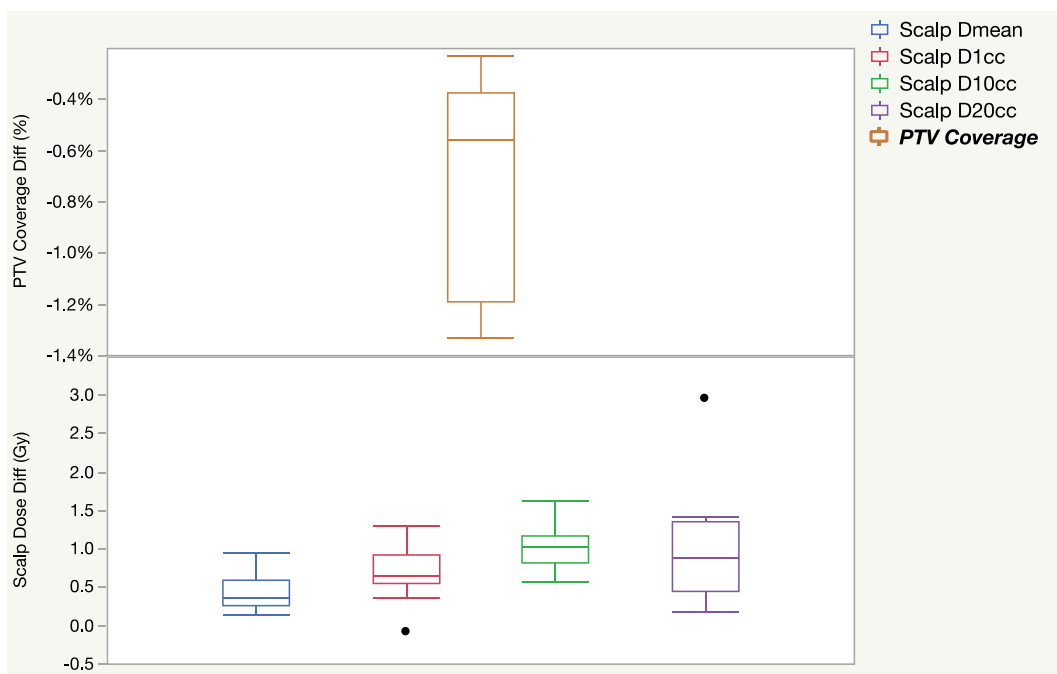

## RESULTS

### Plan Dosimetry Evaluation

**Figure 2** shows the difference in PTV coverage and scalp dose when comparing dose calculated with TTField electrodes in place against dose calculated without electrodes for 10 patients. In general, the calculated dose with the presence of electrodes decreased PTV coverage by  $0.7 \pm 0.4\%$  in the treatment planning system. Dose to the scalp were slightly elevated when electrodes were taken into consideration during dose calculation. Mean scalp dose, as measured by the D1cc, D10cc, and D20cc were on average 0.5–1 Gy higher. Wilcoxon signed rank tests for all

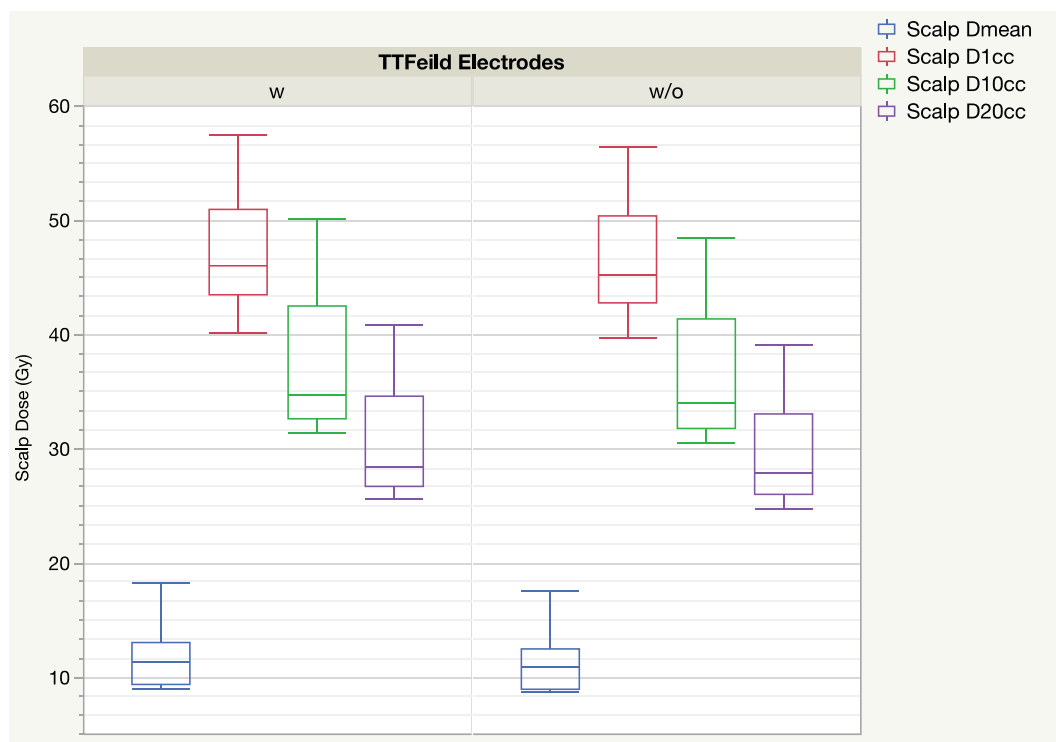

**FIGURE 1** | Measurements on deep dose impact from tumor treating fields (TTFields) electrodes conducted using the Delta4 volumetric-modulated-arc-therapy QA platform. Blue and amber overlays showing the position and directions of orthogonal detector panels 1 and 2.

**FIGURE 2** | Dosimetric differences in PTV coverage and scalp dose as a result of including tumor treating field electrodes into dose calculation for 10 patients.

**FIGURE 3** | Boxplot of scalp DVH parameters from treatment planning system comparing with and without tumor treating field (TTField) electrodes.

paired dosimetric parameters and the differences between with and without TTFields electrodes indicated were all statistically significant, with  $p$ -values ranging from 0.002 to 0.004.

**Figure 3** shows the distribution of scalp mean dose, D1cc, D10cc, and D20cc of plans calculated with and without taking electrodes into consideration. The impact of the electrodes on the distribution of the scalp DVH parameter is generally small. Doses calculated with electrodes were numerically higher than without, but the paired differences were small although statistically significant.

### Physical Measurements—Surface Dose

**Figure 4** shows the surface dose increase due to the presence of the electrodes. The surface dose measured at different gantry angles were compared to measurement done at the same condition but without the electrodes, and the results were plotted against gantry angles. It is evident that the presence of the TTFields electrode introduced additional buildup effect that increased surface dose directly underneath. This buildup effect was the most pronounced at gantry 0, i.e., beam being perpendicular to the surface, causing surface dose to be 2.1 times measurement without TTFields electrodes. At large angles, i.e., beam being near tangent to the surface, the buildup factor is smaller, but still increases the surface dose underneath the electrode by approximately 30%.

**Figure 5** shows the surface dose measurement comparison for five VMAT plans (12 VMAT arcs) with and without TTFields electrodes. In all cases, the presence of TTFields electrodes significantly increased the surface dose measured by parallel plate

**FIGURE 4** | Surface dose increase factors plotted for different beam incident angles. Factors are normalized to the measurement taken at the same gantry angle without the electrodes.

chamber, by a mean ratio of 2.2 (range, 1.7–2.6), which was a larger effect than was measured in the open beam condition.

### Physical Measurements—Deep Dose

Deep dose measurements for all five patients' plans were shown in **Figure 6**. Regions around the center of the panels showed negative dose deviations, which corresponded to the locations that was shadowed by the TTFields electrodes. The pattern of the cold regions align well with the distribution of the individual electrodes

on the TTFields device. Most regions affected by TTFields electrodes showed a dose decrease of 1–2%. Because the radius of the phantom is similar to that of an adult's head, the impact on deep

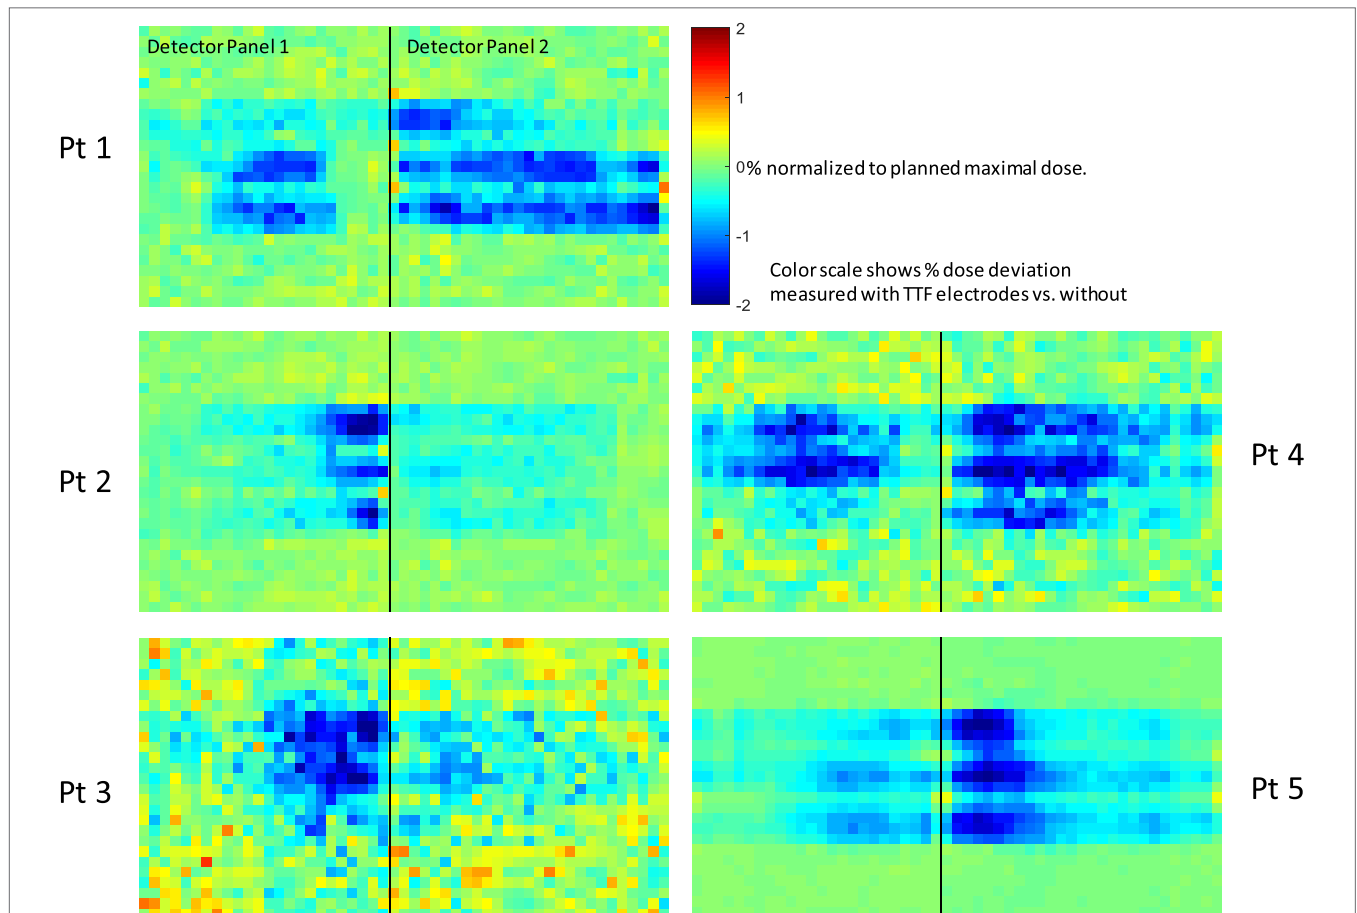

dose in a clinical scenario where patient receives treatment with TTFields electrodes is likely to be in the similar range.

## DISCUSSION

Tumor treating fields has been gaining popularity in recent years as a treatment option for glioblastoma after completion of standard postoperative chemoradiation. In the clinical trials showing efficacy of TTFields, patients were prescribed to wear the device for greater than 18 h daily; this is not always feasible for patients. Utilizing the device in the setting of 6 weeks of daily radiation treatments may increase the logistical challenges to achieving high levels of compliance. From a clinical trial design standpoint, removing and replacing the electrodes on a daily basis to accommodate radiation may confound the outcome and increase skin irritation, since the electrodes are typically exchanged every 2–3 days. As such, before embarking on a trial to evaluate the possible synergy of these treatment modalities, it is necessary to quantify the impact of these high-density electrodes on the dosimetry of radiation treatment. The present work provides radiation oncologists and physicists some quantitative guidelines on how to safely design treatment plans for the delivery of concurrent therapy.

**FIGURE 5** | Surface dose comparison for volumetric-modulated-arc-therapy deliveries for 12 arcs and 5 patients. On average, the ratio of surface dose between measurement with tumor treating field (TTFields) electrodes and the one without is 2.23.

**FIGURE 6** | Deep dose measurement conducted using Delta4™ quality assurance device. Black line separates the two measurement planes orthogonally arranged in the cylindrical phantom. Pixels are color coded according to the dose difference relative to the maximal dose in the plan. The scales are from –2% (deep blue) to +2% (deep red).

The results demonstrate that the presence of TTFields electrodes has minimal impact on the deep dose to the planning target volume, which suggests that tumor dose would be unlikely to be compromised due to shadowing from the electrodes. Importantly, the physical deep dose changes measured in the phantom agreed with the dosimetric changes, which is reassuring.

This dosimetric and physical dose measurement agreement was not seen in the quantification of skin dose. While no significant increase was observed in the treatment planning system using commonly evaluated DVH parameters such as scalp D1cc, physical measurements of surface dose increased when the electrodes were adhered to the surface by a factor of 1.3–2.6 in open field and VMAT deliveries. This result shows that additional caution must be taken into account for skin dose increase, which might not be evident in the DVH evaluation process. Scalp sparing could be improved by using a 3 mm contraction ring from the skin surface with additional penalizing constraints during VMAT optimization. The detailed effectiveness and trade-offs for using this technique is currently under investigation.

The results also provided an important guideline for the design of radiation treatment plans for treating glioblastoma patients concurrently with the TTFields device. Due to the increased dose measured at the surface, some effort to spare the scalp may be clinically meaningful. Further, scalp dose constraints may need to be more conservative, in anticipation of the additional skin dose below the electrodes. While the toxicity rates will have to be measured prospectively, a conservative recommendation might be to limit skin dose during treatment planning between 30 and 50% of published dose constraints.

There are several limitations of the current study. First, only one dose calculation algorithm was used in the planning study. For other dose calculation algorithms and treatment planning systems, the difference between calculated dose with and without TTFields electrodes could be different, especially for the surface dose. Treatment planning systems have long had difficulty with accurate estimation of surface dose. However, as dose calculation algorithms improve, the accuracy of calculated skin/scalp dose is likely to be closer to measurements and may provide a more accurate skin dose estimation during treatment planning.

Second, although a parallel plate chamber was selected to ensure that dose is only measured at a very small depth (~1 mm), the measurement is limited by the large area of parallel plate chamber in the direction parallel to the surface. This limitation can partially explain why VMAT deliveries had a higher surface dose increase than the largest increase found in open field delivery. The ionization chamber used in this study has an active collection volume with a diameter of ~1 cm, while VMAT deliveries consist of many small and rapidly changing fields and segments. For deliveries without TTFields electrodes on top of the chamber window, when the chamber volume is partially exposed to a VMAT segment, only charges generated in the partial volume are collected but averaged over the entire volume. This results in a partial volume effect, which leads to an under-response with VMAT deliveries. When TTFields electrodes were placed on top of the parallel plate chamber's

collection volume, they served to act as a buildup material. In the same small segment scenario described above, even though only a part of the chamber is exposed to primary photons, secondary electrons generated from the TTFields electrodes can still be scattered into the part of collection volume that is not exposed to the primary photon fluence. This effectively increases the parallel plate chamber's collection efficiency under the partial volume condition, which compensates for the partial volume effect and reduces the detector's under-response. When the ratios between measurement with and without TTFields electrodes were calculated, the smaller denominator as a result of more pronounced partial volume effect could make the calculated ratio larger than actual value measured with a true point dose measurement.

When measuring deep dose, the TTFields electrodes were arranged to be in the same plane as the beam's central axis of rotation. This maximized the likelihood of the electrodes being in the beam path. Therefore, the deep dose impacts detected in the above measurements likely represents a "worst case scenario." In an actual clinical setting with patients wearing TTFields electrodes, the arrangement of TTFields electrodes will be non-coplanar and more random due to self-replacement by the patients, and the dosimetric impact is likely to be less than what was observed in the present work.

It is also important to note that the TTFields electrodes patches are disposable and regularly changed by patients. As the location of the electrodes will vary over the duration of RT, an effective averaging of the skin dose hot spots will be observed, which may reduce the maximal skin doses seen in any given region of the scalp. However, due to the uncertainty of this "hot spot averaging," and in the absence of prospective data in patients, the authors recommend conservative scalp dose guidelines in clinical trials, with utilization of methods to reduce scalp dose as much as possible.

## CONCLUSION

In this study, the impact from TTField electrodes on the dosimetry of VMAT treatment plans for patients with glioblastoma was quantitatively evaluated in two ways: (1) in the treatment planning system using advanced dose calculation algorithm and (2) using physical measurements on surface and deep doses. In general, the presence of electrodes decreases deep dose by ~1–2% confirmed by both treatment planning dose calculation and physical measurements. Skin dose underneath the electrodes at ~1 mm depth were measured to be 1.3 – 2.6 times the dose measured without the electrodes, representing an increase by 30% to 160%; this effect was not evident from evaluation of scalp DVH parameters in the treatment planning system. The present work provides evidence that radiation doses to planning target volumes is not significantly changed due to the presence of TTFields electrodes, although the impact on skin dose was notable. As clinical trials to evaluate the potential synergy between TTFields and cranial irradiation are developed, care should be taken during treatment planning to reduce maximum scalp and skin doses well below published guidelines to reduce the risk of potential toxicity.

## Abstract

**Background** Tumor treating fields (TTF) harness magnetic fields to induce apoptosis in targeted regions. A 2015 landmark randomized phase III trial of newly diagnosed glioblastoma (GBM) patients demonstrated TTF + temozolomide to be superior to temozolomide alone. Given these results, we sought to assess practice patterns of providers in TTF utilization for GBM.

**Methods** A survey was administered to practices in the United States self-identifying as specializing in radiation oncology, medical oncology, neuro-oncology, neurosurgery, and/or neurology. Responses were collected anonymously; analysis was performed using Fisher's exact test.

**Results** A total of 106 providers responded; a minority (36%) were in private practice. Regarding case volume, 82% treated at least six high-grade gliomas/year. The provider most commonly certified to offer TTF therapy to GBM patients was the neuro-oncologist (40%), followed by the radiation oncologist (34%); 31% reported no TTF-certified physician in their practice. TTF users were more likely to have high volume, and be aware of TTF inclusion in National Comprehensive Cancer Network (NCCN) guidelines ( $p < 0.05$ ).

**Conclusions** More than 80% of TTF for GBM in the United States is performed by groups who treat at least six high-grade gliomas per year; unfortunately more than 30% were in practices bereft of anyone certified to offer TTF therapy. These results indicate that there remains fertile soil for TTF therapy nationwide to be introduced into practices for GBM treatment. Providers seeking to refer newly diagnosed GBM patients for TTF should seek out practices with TTF user-associated characteristics to ensure optimal access for their patients.

## Introduction

Tumor treating fields (TTF) are a low-intensity, intermediate-frequency, non-invasive and regional antimitotic treatment that harnesses magnetic fields to induce apoptosis in targeted regions [1]. In recurrent glioblastoma (GBM), a phase III trial demonstrated TTF as superior to active chemotherapy with regard to toxicity/quality of life, and comparable with regard to overall survival; this finding led to the approval of TTF for recurrent GBM by the Food and Drug Administration (FDA) in 2011 [2, 3]. Less than 4 years later, interim analysis of a phase III trial of newly diagnosed GBM patients found TTF + temozolomide superior to temozolomide alone in both overall survival and progression-free survival, leading to FDA approval of TTF for newly diagnosed GBM as well as the adoption of TTF in the 2016 National

Comprehensive Cancer Network (NCCN) guidelines [3, 4]. Given these findings, we sought to assess practice patterns and trends of providers in the utilization of TTF for GBM in the United States.

## Methods

A survey designed through the Oregon Clinical and Translational Research Institute and approved by the Oregon Health and Science University Institutional Review Board was administered in 2017 to practices in the United States which self-identified as specializing in radiation oncology, medical oncology, neuro-oncology, neurosurgery, and/or neurology. The survey was designed and hosted by Research Electronic Data Capture (REDCap), and contained screening questions to ensure respondents were currently practicing and not in training [5]. 2483 physicians were contacted by email and invited to complete the survey.

Responses were collected anonymously; the survey was constructed to identify characteristics of each respondent's typical practice patterns and to assess responder knowledge of appropriate clinical scenarios for TTF, knowledge of TTF therapy status on current NCCN guidelines, and personal approaches for patients with recurrent GBM. Demographic questions included the practicing status of the physician, profession, description of practice setting, year of completed residency/fellowship training, number of physician-partners in immediate practice group/department, region of practice, number of high-grade gliomas treated per year, and the presence of a certified TTF therapy provider. Based on responses, participants were categorized as "users" or "nonusers" of TTF for newly diagnosed GBM. Utilization of TTF was correlated with practice patterns using Fisher's exact test.

## Results

A total of 106 providers responded; 95% were practicing physicians, most commonly representing Missouri (8.9%), Massachusetts (7.9%), California (6.9%), Pennsylvania (5.9%), Oregon (5.9%), and Illinois (5.9%). The most common responders were radiation oncologists (75%) and neuro-oncologists (22%); medical oncologists (3%) and neurosurgeons (1%) comprised the remaining responders. The average number of physician-partners in a responder's practice group was 7.6; a minority (36%) were in private practice. 81% of responders were aware that TTF therapy is listed on current NCCN guidelines; the remaining responders were unaware.

With regard to case volume, only 18% treated 0–5 high-grade gliomas per year, while 24% treated 6–10 annually,

and 58% treated at least 10 high-grade gliomas annually. The provider most commonly reported as certified to offer TTF therapy to GBM patients was the neuro-oncologist (40%), followed by the radiation oncologist (34%); 31% reported no physician in their practice being certified to administer TTF therapy (Fig. 1).

Users of TTF were more likely to have greater high-grade glioma volume ( $> 10$  GBM patients/year;  $p = 0.024$ ; relative risk 1.5), be knowledgeable of TTF inclusion on the 2016 NCCN guidelines ( $p < 0.0001$ ; odds ratio = 10.4; relative risk = 3.0), and specialize in radiation oncology or neuro-oncology ( $p = 0.016$ ) (Table 1). There was no difference in years of practice, location of training, geographic location of practice, number of physician-partners in immediate practice, or academic versus private practice setting between users and nonusers of TTF.

## Discussion

With the most recent evidence firmly in support of TTF plus temozolomide increasing median overall survival in newly diagnosed GBM by 4.9 months over temozolomide alone (more than a 30% increase in life span), it is becoming more imperative for TTF to be made available to GBM patients [6]. We sought to assess the nationwide trends and practice patterns of TTF application in the United States.

Our results indicate that TTF for newly diagnosed GBM in the United States is administered by providers who are knowledgeable of its inclusion in the 2016 NCCN guidelines, have elevated high-grade glioma volume, and specialize in radiation oncology or neuro-oncology. Knowledge of TTF inclusion in the 2016 NCCN guidelines roughly tripled the likelihood of TTF utilization for newly diagnosed GBM, and GBM volume of at least 10 patients/year increased the

**Table 1** Association between clinical practice variables and use versus non-use of tumor treating fields (TTF) for newly diagnosed glioblastoma (GBM)

Clinical demographic	Clinical practice variable	TTF nonuser	TTF user	P value
Practice setting	Academic	18 (58.1%)	46 (65.7%)	0.462
	Private practice	13 (41.9%)	24 (34.3%)	
GBM patients treated yearly	Fewer than 10	19 (61.3%)	23 (32.9%)	0.024
	10 or more patients	12 (38.7%)	47 (67.1%)	
Number of physician-partners in immediate practice	0–4	16 (51.6%)	26 (37.1%)	0.484
	5–9	8 (25.8%)	23 (32.9%)	
	10+	7 (22.6%)	18 (25.7%)	
Subspecialty	Radiation oncology	27 (87.1%)	48 (68.6%)	0.016
	Medical oncology	2 (6.5%)	1 (1.4%)	
	Neuro-oncology	2 (6.5%)	20 (28.6%)	
	Neurological surgery	0 (0%)	1 (1.4%)	
Years of independent practice	0–4	3 (9.7%)	12 (17.1%)	0.112
	5–9	4 (12.9%)	16 (22.9%)	
	10–19	7 (22.6%)	22 (31.4%)	
	20+	17 (54.8%)	20 (28.6%)	
Awareness of TTF therapy on National Comprehensive Cancer Network (NCCN) guidelines	Yes	17 (54.8%)	65 (92.9%)	<0.001
	No	14 (45.2%)	5 (7.1%)	

likelihood of TTF utilization by roughly 50%. Despite widespread implementation of TTF, there remains a substantial portion of medical practices (31%) unable to offer TTF as a treatment modality to GBM patients, and 1/5 of providers remain unaware of the inclusion of TTF in the NCCN guidelines for newly diagnosed GBM. Furthermore, because more than 80% of TTF is performed by groups who treat at least six high-grade gliomas per year (with nearly 60% performed by groups treating more than 10 high-grade gliomas/year), it becomes increasingly imperative for GBM patients to be referred towards high-volume centers to optimize their likelihood of being offered TTF as a treatment modality. This becomes problematic when examining the racial and socioeconomic realities of brain tumor patients, as poor and nonwhite patients are the least likely to be referred to high-volume centers for neuro-oncologic care [7, 8].

Limitations of this study include its low response rate, given that only 106 of the 2483 physicians contacted chose to participate (4.3% response rate); this is unfortunately similar to low response rates reported in studies involving other subspecialties [9]. Because responses were in the format of multiple choice, the full range of opinions may not have been adequately captured. Third, survey fatigue can result in responses that are not genuine; we sought to curb this by not offering an incentive (financial or otherwise) to complete the survey that we hope maximized the rate of legitimate responses. Finally, an important consideration is the lack of granularity in addressing the socioeconomic and racial demographic of patients, the latter of which may impact the applicability of randomized controlled trials comprised of

inadequately low nonwhite patient participation, as has been recently noted in localized prostate cancer [10, 11].

In conclusion, the vast majority of TTF for GBM in the United States is administered by neuro-oncologists and radiation oncologists, usually in an academic setting involving 7–8 physician-partners. However, one-fifth of providers were unaware of TTF therapy being listed on current NCCN guidelines for GBM treatment, and more than 30% were in practices bereft of anyone certified to offer TTF therapy. These results indicate that opportunities exist for TTF therapy nationwide to be introduced into practices for GBM treatment. Given the continued promising results of TTF for newly diagnosed and recurrent GBM in clinical trials thus far, this opportunity should be seized energetically [6, 12]. Providers seeking to refer newly diagnosed GBM patients for TTF should seek out practices with multiple characteristics (i.e. high volume, NCCN guideline inclusion knowledge, radiation oncologist or neuro-oncologist, etc.) to ensure optimal TTF access for their patients.

**Abstract**

**Background:** Tumor treating fields (TTF) have become an important, evidence-based modality in the treatment of glioblastoma (GBM). In patients requiring cardiac pacemakers, TTF therapy is complicated by theoretical concerns regarding possible electrical interaction between the devices.

**Case Description:** A 57-year-old man with past medical history of sick sinus syndrome requiring cardiac pacemaker implantation suffered an acute neurologic change associated with a left parieto-occipital lesion, which was found to be GBM. After completion of guideline-concordant chemoradiation, he chose to undergo TTF therapy. Because of the absence of cardiac symptoms and the theoretical risk of far-field sensing by the pacemaker of the TTF device (potentially resulting in pacemaker inhibition), the pacemaker was turned off prior to receiving TTF. Following TTF implementation, the patient responded well; he remains alive more than 25 months following his GBM diagnosis, exceeding the median 20.9 month survival of the recently completed phase III TTF randomized clinical trial for newly diagnosed GBM. Furthermore, he has exhibited neither cardiac morbidity nor adverse scalp reactions to TTF therapy.

**Conclusions:** The first reported case of successful TTF administration in a GBM patient with a previously implanted cardiac pacemaker may allay the concerns of neuro-oncologists, cardiologists, radiation oncologists, and all certified TTF prescribers regarding the applicability of TTF in suitable candidates with preexisting cardiac pacemakers. This case indicates that TTF therapy may be efficacious in patients with indwelling MRI-conditional cardiac pacemakers turned to the off position, and that physical removal of the pacemaker is not necessary prior to starting TTF.

## Introduction

Conclusion of a recent phase III trial has demonstrated that tumor treating fields (TTF) significantly improve overall survival and progression-free survival in glioblastoma (GBM), which has led to its approval by the Food and Drug Administration (FDA), its adoption in the National Comprehensive Cancer Network Guidelines, and its increasing utilization throughout the United States (1-3). For GBM patients with cardiac comorbidity necessitating pacemaker placement, TTF therapy (Optune; Novocure Ltd., St. Helier, United Kingdom) presents certain considerations which may make practitioners reluctant to recommend its utilization. The first is the theoretical risk of electrical interference between the TTF current and the cardiac pacemaker, as indicated on the Optune website: "Optune has not been tested in people with implanted electronic devices, which may cause the devices not to work properly". The second consideration is the perceived inability to use MRI guidance (secondary to the presence of the pacemaker) for planning of the TTF cranial grid array prior to treatment initiation. We report on a patient with a previously implanted cardiac pacemaker who successfully underwent TTF therapy for GBM.

### Illustrative Case

Our patient was a 57-year-old man with a medical history of sick sinus syndrome for which he underwent a dual chamber bipolar pacemaker (Medtronic A2DR01 Advise DR MRI pulse generator with two Medtronic 5076 CapSureFix Novus leads – one atrial and one ventricular; Medtronic, Inc., Minneapolis, MN) implantation in 2015. Unlike older pacemaker models, this model is MRI-conditional, approved by the FDA for 1.5T and 3T full body MRI scan based on the results of a 2015 randomized trial (4).

Shortly afterwards, the patient suffered an acute onset of cognitive changes for which he was brought to the hospital. Although head CT was negative for hemorrhage, brain MRI revealed a left medial temporal lesion and hippocampal cerebritis. Following stabilization, he received operative neurosurgical intervention, which revealed anaplastic astrocytoma. Postoperatively, he declined both radiation therapy (RT) and systemic chemotherapy and decided to pursue alternative treatment. Unfortunately, four months later, he returned to the emergency room with headaches and weakness. Imaging revealed midline shift and a left parieto-occipital recurrent lesion. He underwent a second resection, which revealed GBM (vimentin positive, p53 positive, IDH1 positive, Ki-67 10-20%). Postoperatively, he was referred to radiation oncology and neuro-oncology, and underwent both RT and systemic temozolomide, completing RT two months after surgery. Two months later, he was seen in follow-up in Radiation Oncology clinic and elected to pursue TTF therapy.

Because of the theoretical risk of far-field sensing by the pacemaker of the TTF device, which could potentially have resulted in pacemaker inhibition, the patient underwent a testing session involving cardiologic monitoring, where the pacemaker was confirmed to be turned off (to OOO mode). The patient tolerated this procedure well, as he was in his own native rhythm. He understood that we could

not be certain that there would be no interference between the TTF and pacemaker, and elected to proceed with TTF despite this known risk.

Following TTF implementation, the patient continued primarily with concomitant systemic temozolomide, as he was unable to tolerate bevacizumab. At last follow-up in our multidisciplinary RADIANS (RADiation oncology And NeuroSurgery) multidisciplinary clinic, he remains alive more than 26 months following his GBM diagnosis, exceeding the median 20.9 month survival of the TTF + temozolomide group in the final analysis of the recently completed phase III randomized clinical trial (1, 5). Furthermore, he has exhibited no adverse scalp reactions to TTF therapy nor any cardiac morbidity. Such an excellent response despite receiving no GBM therapy besides temozolomide is indicative that he suffered no defects in the functionality of his TTF device despite the presence of his cardiac pacemaker.

## Discussion

The clinical application of an electrical device to a patient with a preexisting cardiac pacemaker is not a novel concept, as it has successfully been achieved safely and efficaciously in patients requiring deep brain stimulation (DBS) electrode implantation for treatment of medically refractory Parkinson's disease since 2004 (6-7). The greatest theoretical risk is inappropriate shock due to electrical interference (8). This has been seen in reports of cardiac pacemaker discharge at the time of implantation in a patient with preexisting DBS leads, most frighteningly manifesting as microwave diathermy along the path of the DBS lead in a patient, resulting in permanent diencephalic and brainstem lesions concomitant with a vegetative state (9). Another report detailed a patient who underwent a radiofrequency-coupled thalamic stimulator system with an external pulse generator and transmitter; unfortunately, the subcutaneous receiver transmitted the external cardioversion current, resulting in a thalamotomy and the spread of the current to the ventrocaudal nucleus resulting in a central pain syndrome (10). Given such cautionary tales, it is understandable for practitioners to be reluctant to recommend patients with preexisting pacemakers and newly diagnosed GBM having completed concomitant chemoradiation for TTF therapy.

In our patient, open communication between the radiation oncology and cardiology teams regarding TTF in the setting of his pacemaker allowed for a smooth execution of treatment planning where the pacemaker was turned off prior to TTF initiation. Given our patient's underlying cardiac disease (sick sinus syndrome), cardiology believed there was no significant risk of turning his pacemaker off; this estimation has been proven correct by the fact that the patient has demonstrated no cardiac events in the nearly two years since his pacemaker was turned off and has responded very well to TTF. No additions to our patient's baseline cardiology follow-up were recommended by the cardiology team during TTF therapy.

This case brings to mind the obvious question regarding the applicability of TTF therapy for GBM patients with pacemakers that cannot be turned off and the optimal strategy in these situations. Similarly complex scenarios have been published previously involving interactions between DBS electrodes and cardiac pacemakers (6-7). In the seminal report, a preoperative testing session was performed where programming of a test DBS model was performed in the proximity of the patient to evaluate any interaction with their pacemakers utilizing EKG monitoring (6). As in that report, the pacemaker in this patient was a “demand” pacemaker, typical of the vast majority of modern-day implanted pacemakers, which are bipolar in configuration (6). Bipolar devices involve the dipole used for sensing to be located within the heart; this is in contrast to unipolar devices in which the dipole is located between the heart and the pacemaker generator in the chest. For a unipolar device, the metal encapsulating the pacemaker in the chest is electrically active (participating in the sensing circuit), while for a bipolar device metal in the chest is excluded from the sensing circuit because that circuit is composed of the dipole in each lead in the heart, as the anode and cathode are on the lead itself (6). Because the bipolar configuration is less susceptible to oversensing, we believe that bipolar leads are preferable in all cases. Since the bipolar configuration senses within the heart rather than between the heart and the chest wall, the bipolar configuration is less likely to sense extraneous signals. In this patient population, we would recommend that the treating cardiologist maintain bipolar programming; if the cardiologist believes that unipolar programming is required, testing should be performed to rule out TTF device-induced oversensing. Noteworthy is that for patients with pacemakers not compatible with MRI, the cranial grid array mapping for TTF can be performed using CT imaging. Additionally, many centers will perform clinically indicated MRIs on patients with “legacy” i.e. non-MRI conditional pacemakers (11). We would recommend that for patients with more severe cardiac pathology than our patient that cardiology document the cardiac risk per year of turning the pacemaker off, which could

then be compared to the survival benefit of TTF for GBM; depending on the results, cardiology follow-up during TTF therapy may need to be intensified.

In conclusion, our experience with the first manuscript reporting successful TTF administration in a GBM patient with a previously implanted MRI-conditional cardiac pacemaker may allay the concerns of neuro-oncologists, cardiologists, radiation oncologists, and all certified TTF prescribers regarding the applicability of TTF in suitable candidates with preexisting cardiac pacemakers; noteworthy is a previous abstract which described TTF for GBM in three unspecified patients with indwelling pacemakers of unclear specifications and follow-up of unspecified duration (12). This case indicates that TTF therapy may be efficacious in patients with indwelling cardiac pacemakers turned to the off position, and that physical removal of the pacemaker is not necessary prior to starting TTF.

## Tumour Treating Fields (TTFs) for recurrent and newly diagnosed glioblastoma multiforme

Farhan A. Mirza, Muhammad Shahzad Shamim

### Abstract

In the last decade, significant advances have been made in Glioblastoma Multiforme treatment with the novel use of alternating electrical fields, also termed as tumour treating fields (TTFs). This modality has shown promising results in recurrent and newly diagnosed GBM patients, and according to some, may soon be considered an addition to the previously known 'trifecta' of GBM standard of care, i.e., surgery, chemo and radiation therapy. Here we review the existing data on TTF for both recurrent and newly diagnosed GBM. This review does not discuss the limitations of TTF, especially from compliance and cost point of view.

**Keywords:** Glioblastoma, Tumour Treating Fields, Alternating Electric Fields, Progression Free Survival, Overall Survival

### Introduction

In the first in vivo study involving Tumour Treating Fields (TTF) was tested in ten patients with recurrent GBMs using non-invasive transducer arrays attached to the scalp, with significant improvement noted in time to tumour progression (TTP) [26.1 vs 9.5 weeks], progression free survival (PFS) at 6 months [50% vs 15.3%], and overall survival (OS) [median 62.2 vs 29.3 weeks], without any systemic toxicity.<sup>1</sup> In 2009, the same group performed a second pilot trial to understand the efficacy of TTFs in newly diagnosed patients in combination with standard adjuvant TMZ, and again noted very promising results (Median PFS [155 vs 31 weeks] and improved median OS [> 39 vs 14.7 months]).<sup>2</sup>

### Review of Evidence

We queried the PubMed database with the phrases 'tumour treating fields in glioblastoma' and 'alternating electric fields in brain tumours'.

**Figure:** An example of TTF applied on a patient.<sup>13</sup>

Abstracts of articles describing this treatment modality were reviewed. Articles addressing use of tumour treating fields in high grade gliomas were reviewed.

### Role in Recurrent GBM

Median time to recurrence for GBM is approximately seven months and median survival 15-18 months. Repeat craniotomy and Bevacizumab have shown to be beneficial in the recurrent setting.<sup>3</sup> Despite this, about 60% of patients relapse on Bevacizumab, can have serious side effects, develop resistance to the drug, and also fail to respond to any further chemotherapy.<sup>4</sup>

In 2012, Stupp et al published their results on the first Phase III trial of 237 patients studying the effects of TTFs alone, compared with standard chemotherapy

regimens in recurrent GBM.<sup>5</sup> Thirty-six patients received bevacizumab, 36 received nitrosureas, 12 received temozolomide, and 33 received other agents. It was noted that TTFs alone were comparably effective and had lower toxicity profile and better quality of life. This landmark study led to the FDA approval of NovoTTF-100A™ System (Novocure, Ltd., Haifa, Israel) as stand alone treatment for recurrent GBMs. Subsequently several post-hoc analyses of this trial were conducted which showed subsets of patients in whom TTFs alone resulted in improved OS compared to second line chemotherapy (11.8 vs 9.2 months).<sup>6</sup> Rulesh et al, in 2012, published their series of twenty patients with recurrent GBM who had been treated with TTFs between 2004 and 2007.<sup>7</sup> They reported four long term survivors who were still alive at the time of publication. According to the authors, this was the first clinical study to have looked at the use of TTFs in recurrent GBM. However, the data reported on the original patients was quite limited and molecular characteristics of tumours in the survivors were not elucidated, hence not many conclusions can be drawn from it. Two trials are currently for recurrent GBM refractory to bevacizumab, and bevacizumab naive recurrent GBM.<sup>8,9</sup>

### Role in Newly Diagnosed GBM

Stupp et al published their first randomized control trial on this subject in 2015.<sup>10</sup> In this study, they used TTFs in combination with maintenance TMZ and compared this group with standard TMZ administration. 695 patients from 83 centers across the world were included between July 2009 and November 2014. Significant improvement in progression free survival and overall survival was noted: 7.1 months (95% CI, 5.9-8.2 months) in the TTF plus TMZ group and 4 months (95% CI, 3.3-5.2 months) in the TMZ alone group. P= 0.001. Median overall survival was 20.5 months (95% CI, 16.7-25.0 months) in the TTF plus TMZ group and 15.6 months (95%CI, 13.3-19.1 months) in the TMZ group P= 0.004). Given this improvement in survival, it has been suggested to include this as part of standard of care for newly diagnosed GBM, in addition to the Stupp Protocol.<sup>11</sup>

In non-methylated MGMT promoter, TMZ is not considered a treatment option due to its resistance. A recent study by Clark et al effectively showed the utility of TTFs in both methylated and non-methylated cells.<sup>12</sup> As such, in patients with non-methylated MGMT promoter, the application of TTFs after radiation should be effective. It is also

interesting to note that tumour cells may develop some resistance to TTFs.

### Conclusion

The introduction and popularization of tumour treating fields is a remarkable development in GBM treatment since the introduction of the Stupp protocol in 2005. It offers an entirely new area for research and possible options for treatment. So far, studies have shown promising results with this treatment modality, with the added benefit of minimal toxicity and improved quality of life compared to standard chemoradiation options.

**Abstract:** Tumor treating fields (TTFields) represent a novel FDA-approved treatment modality for patients with newly diagnosed or recurrent glioblastoma multiforme. This therapy applies intermediate frequency alternating electric fields with low intensity to the tumor volume by the use of non-invasive transducer electrode arrays. Mechanistically, TTFields have been proposed to impair formation of the mitotic spindle apparatus and cytokinesis. In order to identify further potential molecular targets, here the effects of TTFields on Ca<sup>2+</sup>-signaling, ion channel activity in the plasma membrane, cell cycle, cell death, and clonogenic survival were tested in two human glioblastoma cell lines in vitro by fura-2 Ca<sup>2+</sup> imaging, patch-clamp cell-attached recordings, flow cytometry and pre-plated colony formation assay. In addition, the expression of voltage-gated Ca<sup>2+</sup> (Ca<sub>v</sub>) channels was determined by real-time RT-PCR and their significance for the cellular TTFields response defined by knock-down and pharmacological blockade. As a result, TTFields stimulated in a cell line-dependent manner a Ca<sub>v</sub>1.2-mediated Ca<sup>2+</sup> entry, G<sub>1</sub> or S phase cell cycle arrest, breakdown of the inner mitochondrial membrane potential and DNA degradation, and/or decline of clonogenic survival suggesting a tumoricidal action of TTFields. Moreover, inhibition of Ca<sub>v</sub>1.2 by benidipine aggravated in one glioblastoma line the TTFields effects suggesting that Ca<sub>v</sub>1.2-triggered signaling contributes to cellular TTFields stress response. In conclusion, the present study identified Ca<sub>v</sub>1.2 channels as TTFields target in the plasma membrane and provides the rationale to combine TTFields therapy with Ca<sup>2+</sup> antagonists that are already in clinical use.

**Keywords:** glioma; alternating electric field therapy; Ca<sup>2+</sup> signaling; programmed cell death; clonogenicity; L-type Ca<sup>2+</sup> channel; benidipine

## 1. Introduction

Tumor Treating Fields (TTFields) therapy, developed by the company NovoCure (Haifa, Israel) is a new modality of anti-cancer therapy which has been FDA-approved for newly diagnosed and recurrent glioblastoma multiforme and is currently evaluated for several other tumor entities. TTFields apply alternating intermediate-frequency (200 kHz) sine wave-electric fields with low field strength (1–3 V/cm) to the tumor with the help of non-invasive ceramic transducer electrode arrays (for glioblastoma patients mounted on the shaved scalp). TTFields were usually administered 20–24 h/day

for several months [1] concomitantly to temozolomide maintenance therapy after surgical resection of the glioblastoma and subsequent radiochemotherapy with temozolomide. A phase III clinical trial on recurrent glioblastoma comparing TTFields monotherapy with physician's choice chemotherapy indicates that the efficacy of TTFields is similar to chemotherapy with improved toxicity profile [1]. The 6-year-follow-up of a prospective randomized multicenter phase III trial on newly diagnosed glioblastoma comparing standard temozolomide maintenance therapy with standard therapy plus TTFields electrotherapy indicates a significant improvement of progression-free and overall survival by TTFields [2]. Importantly, the adverse side effects of TTFields therapy are restricted to mild to moderate skin rash beneath the transducer arrays [1,3]. Combined these clinical data indicate that TTFields electrotherapy is an effective and safe treatment modality for glioblastoma patients increasingly offered to patients in good performance status willing to wear the electrode arrays.

TTFields reportedly target mitosis and cytokinesis [4–7]. Mechanistically, TTFields have been proposed to align proteins possessing high intramolecular dipole moments such as tubulin dimers [6] and septins [7] which counteracts proper formation of the mitotic spindle apparatus and positioning of the cytokinetic furrow, respectively. In addition, dielectrophoretic forces in areas of non-uniform TTFields as proposed to occur at the cytokinetic furrow within the dividing cells have been postulated to trap polar macromolecules and organelles and to impair their symmetrical distribution between daughter cells. As a consequence, TTFields induce aberrant metaphase exit, improper chromosome segregation and mitotic catastrophe eventually resulting in cell death [8].

By inhibiting mitosis and cytokinesis, TTFields in particular target fast proliferating cells which results in a certain tumor specificity. Not surprisingly, besides glioblastoma, several other tumor entities such as skin, breast, pancreatic, lung, and ovarian cancer have been reported to react on TTFields in vitro [5–7,9–14], in preclinical in vivo models [5,9,12,13,15–17] or in clinical pilot studies [9,18–20]. Notably, best, i.e., most effective TTFields frequency and field strength differ between the different tumor entities with a best frequency of 200 kHz for glioblastoma [4,9,21].

Beyond impairment of mitosis and cytokinesis, TTFields reportedly lower metastatic spread of tail vein-injected B16 melanoma cells [15], and sensitize to chemo- [10], targeted [22], or radiation therapy [23]. The latter probably results from TTFields-mediated delay in DNA double strand break repair [23] possibly via downregulation of BRCA1 signaling [14]. Importantly, immunosuppression by dexamethasone seems to attenuate the response of glioblastoma patients to TTFields therapy [24] illustrating the function of the immune system in the tumor control by TTFields. Combined, these data point to a complex biological response to TTFields therapy.

Therefore, the present study aimed to identify molecular TTFields targets beyond the proposed mitotic spindle apparatus or the cytokinesis furrow. Such novel targets might be used as markers for patient stratification in terms of therapy personalization. In addition, the identification of novel molecular pathways that are triggered by TTFields and that confer resistance against the electric field therapy bears the great chance for pharmacological intervention and amplification of TTFields efficacy.

Our study placed emphasis on  $\text{Ca}^{2+}$  signaling and  $\text{Ca}^{2+}$ -regulated cellular processes such as cell cycle or cell death since alternating electrical fields have been demonstrated to interfere with intracellular  $\text{Ca}^{2+}$  signals. For instance, voltage-activated  $\text{Ca}^{2+}$  ( $\text{Ca}_v$ ) channels in the electrosensory organs of sharks are involved in perception of changes in the environmental electrical fields [25]. Likewise in mammalian cells, experimental or environmental alternating electric fields have been demonstrated to evoke intracellular  $\text{Ca}^{2+}$  signals [26–32] that may involve in particular L-type  $\text{Ca}_v$  channels in the plasma membrane (for review see [33–35]). The alpha subunits of the L-type  $\text{Ca}^{2+}$  channels  $\text{Ca}_v1.1$ ,  $\text{Ca}_v1.2$ ,  $\text{Ca}_v1.3$ , and  $\text{Ca}_v1.4$  are encoded by the *CACNA1S*, *-1C*, *-1D*, and *1F* gene, respectively. While  $\text{Ca}_v1.1$  is mainly expressed in the skeletal muscle and  $\text{Ca}_v1.4$  restricted to retina,  $\text{Ca}_v1.2$  and  $\text{Ca}_v1.3$  are expressed in most excitable cells. In brain,  $\text{Ca}_v1.2$  and  $\text{Ca}_v1.3$  are found in the dendrites and soma of neurons where among others they are involved in the excitation-transcription coupling [36]. Notably,  $\text{Ca}_v$  channels are also expressed by glioblastoma cells [37]. Potential downstream targets of  $\text{Ca}_v$  are  $\text{Ca}^{2+}$ -activated high conductance  $\text{BK}_{\text{Ca}}$  [38–41] and intermediate

conductance  $IK_{Ca}$  ( $K_{Ca3.1}$ , SK4)  $K^+$  channels [42–44] that have been reported to contribute to cell migration or therapy resistance of glioblastoma cells. Hence, here we analyzed TTFields-evoked modulation of cytosolic free  $Ca^{2+}$  concentration ( $_{free}[Ca^{2+}]_i$ ) and  $Ca^{2+}$ -dependent ion channel activity in the plasma membrane in individual human glioblastoma cells with the help of a single cell TTFields applicator disclosing a TTFields-stimulated  $Ca^{2+}$  entry that involves  $Ca_v1.2$  channels. In a second step, effects of TTFields on cellular DNA content, mitochondrial membrane potential ( $\Delta\Psi_m$ ) and colony formation were analyzed in dependence on pharmacological  $Ca_v$  blockage with the help of a TTFields cell culture applicator in order to assess cell cycle distribution, asymmetric cell division, cell death, triggering of intrinsic apoptosis, and clonogenic survival.

## 2. Materials and Methods

### 2.1. Cell Culture and Transfection

Human T98G (obtained from American Type Cell Culture Collection (ATCC, Manassas, VA, USA) and U251 (kindly provided by Dr. Luiz Penalva, San Antonio, TX, USA) glioblastoma cells were grown in 10% fetal calf serum (FCS)-supplemented RPMI-1640 (T98G) or DMEM (4500 mg glucose/L, U251) medium. For CACNA1C knock-down, exponentially growing U251 and T98G cells were reversely transfected with a mixture of three Stealth siRNAs (Thermo Fischer Scientific, Waltham, MA, USA) specific for human CACNA1C (HSS187849, HSS187850, HSS187851) or with nt siRNA (*Silencer*®Select Negative Control No. 1 siRNA, #4390844, Ambion™, Thermo Fischer Scientific). Detached T98G and U251 cells (250,000 in 2.5 mL RPMI-1640/10% FCS and DMEM (4500 mg glucose/L)/10% FCS medium, respectively) were added to 500  $\mu$ L of pre-incubated (20 min at room temperature) Opti-MEM medium containing RNAiMAX lipofectamine (6  $\mu$ L, Invitrogen Life Technologies, Carlsbad, CA, USA) and siRNA (25 nM final concentration).

### 2.2. Fura-2 Fluorescence Imaging of Cytosolic Free $Ca^{2+}$ Concentration ( $_{free}[Ca^{2+}]_i$ )

Fluorescence measurements were performed at 37 °C using an inverted phase-contrast microscope (Axiovert 100; Zeiss, Oberkochen, Germany). Fluorescence was evoked by a filter wheel (Visitron Systems, Puchheim, Germany)-mediated alternative excitation at 340/26 or 387/11 nm (AHF, Analysentechnik, Tübingen, Germany). Excitation and emission light was deflected by a dichromatic mirror (409 nm beam splitter, AHF) into the objective (Fluar 40 $\times$ /1.30 oil; Zeiss) and transmitted to the camera (Visitron Systems), respectively. Emitted fluorescence intensity was recorded at 587/35 nm (AHF). Excitation was controlled and data acquired by Metafluor computer software (Universal Imaging, Downingtown, PA, USA). The 340/380-nm fluorescence ratio was used as a measure of  $_{free}[Ca^{2+}]_i$ . Control, CACNA1C- or nt siRNA-transfected T98G and U251 cells (48 h after transfection) were incubated with fura-2/AM (2  $\mu$ M for 30 min at 37 °C; Molecular Probes, Goettingen, Germany) in RPMI-1640/10% FCS and DMEM/10% FCS medium, respectively.  $_{free}[Ca^{2+}]_i$  was recorded at 37 °C during superfusion with  $Ca^{2+}$ -containing NaCl solution (in mM: 125 NaCl, 32 HEPES, 5 KCl, 5 D-glucose, 1  $MgCl_2$ , 1  $CaCl_2$ , titrated with NaOH to pH 7.4), with  $Ca^{2+}$ -free NaCl solution (in mM: 125 NaCl, 32 HEPES, 5 KCl, 5 D-glucose, 1  $MgCl_2$ , 0.6 EGTA, titrated with NaOH to pH 7.4), or with  $Ca^{2+}$ -containing NaCl solution further containing the L-, N-, T-type  $Ca^{2+}$  channel blocker benidipine or the L-type inhibitor nifedipine (both 1  $\mu$ M, Sigma-Aldrich, Taufkirchen, Germany) before, during and after application of TTFields (200 kHz, 0–2.5 V/cm).

### 2.3. Patch Clamp Recording

Currents of semi-confluent T98G and U251 cells were elicited by 33 voltage square pulses (700 ms each) delivered in 5 mV increments from 0 mV holding potential to voltages between –80 mV and +80 mV and recorded at 37 °C in cell-attached, voltage-clamp mode by an EPC-9 amplifier (Heka, Lambrecht, Germany) using Pulse software (Heka) and an ITC-16 Interface (Instrutech, Port Washington, NY, USA).

Clamp voltages refer to the intracellular face of the plasma membrane. Flow of positive charge out of the cells (or the counter flow of anions) is defined as positive current and depicted as upward deflection of the current tracings. Cells were superfused at 37 °C with  $\text{Ca}^{2+}$ -containing NaCl solution (see above). Borosilicate glass pipettes (4–6 M $\Omega$  pipette resistance; GC150 TF-10, Clark Medical Instruments, Pangbourne, UK) manufactured by a microprocessor-driven DMZ puller (Zeitz, Augsburg, Germany) filled with  $\text{Ca}^{2+}$ -containing NaCl solution (see above) were used in combination with a STM electrical micromanipulator (Lang GmbH and Co KG, Hüttenberg, Germany). Macroscopic cell-attached currents were analyzed by averaging the currents between 100 and 700 ms of each square pulse. In addition to macroscopic cell-attached currents unitary current transitions were characterized for single channel conductance and open probability ( $P_o$ ). The latter was estimated by subtracting the zero current (i.e., the current at no apparent unitary current transition) at a given clamp voltage from the averaged macroscopic current and by dividing the difference by the amplitude of the unitary current transition and by the apparent number of active channels.

#### 2.4. Quantitative RT-PCR

RNA of control, CACNA1C siRNA-, or nt siRNA-transfected U251 and T98G cells (48 h after transfection) was isolated (NucleoSpin<sup>®</sup> RNA kit, Machery-Nagel, Düren, Germany) and reversely transcribed and CACNA1A, -1B, -1C, -1D, -1E, -1G, -1H, -1I, -1S as well as housekeeper  $\beta$ -actin (ACTB)-, pyruvate dehydrogenase beta (PDHB)-, and glyceraldehyde-3-phosphate dehydrogenase (GAPDH)-specific fragments were amplified by the use of SYBR Green-based quantitative real-time PCR (1Step RT qPCR Green ROX L Kit, highQu, Kraichtal, Germany, and QuantiTect Primer Assays QT00054152, QT00077042, QT00053480, QT00076657, QT00063994, QT00043043, QT00075159, QT00021126, QT00000833, QT00095431, QT00031227, Qiagen, Hilden, Germany) in a Roche LightCycler<sup>®</sup> 480 Instrument (Roche, Mannheim, Germany). mRNA abundances were normalized to the geometrical mean abundance of the three housekeepers.

#### 2.5. Analysis of Cell Cycle, DNA Degradation and Aneuploidy

Exponentially growing T98G and U251 cells were treated for 5–7 days with TTFields (200 kHz, 1 V/cm) in the presence of benidipine (0 or 1  $\mu\text{M}$  in 0.1% DMSO), trypsinized, washed, and stained (30 min at room temperature) with propidium iodide (PI, Sigma-Aldrich) in RNase-containing phosphate-buffered saline (PBS) further containing 0.1% Na-citrate, 0.1% triton X-100, and PI (10  $\mu\text{g}/\text{mL}$ ). For cell cycle analysis, DNA amount was recorded by flow cytometry (FACS Calibur, Becton Dickinson, Heidelberg, Germany, 488 nm excitation wavelength) with FL-3 (>670 nm, linear scale) emission wavelength. In addition, DNA content was monitored with FL-2 emission wavelength (585/42 nm, log scale) for determination of sub-G<sub>1</sub> (DNA degradation) and hyper-G (aneuploidy) populations, respectively. Data were analyzed with the FCS Express 3 software (De Novo Software, Los Angeles, CA, USA).

#### 2.6. Determination of Inner Mitochondrial Membrane Potential ( $\Delta\Psi_m$ )

TTFields-treated (5–7 days, 200 kHz, 1 V/cm) and benidipine-co-treated (0 or 1  $\mu\text{M}$  in 0.1% DMSO) T98G and U251 cells were trypsinized, washed, and incubated for 30 min at room temperature in  $\text{Ca}^{2+}$ -containing NaCl solution (see above) containing the  $\Delta\Psi_m$ -specific dye tetramethylrhodamine ethyl ester perchlorate (TMRE, 25 nM, Invitrogen, Karlsruhe, Germany). TMRE-specific fluorescence was measured by flow cytometry with FL-2 (585/42 nm) emission wavelength.

#### 2.7. Colony Formation Assay

To test for clonogenic survival, T98G and U251 were pre-plated (600 cells/well in 12-well plates), co-incubated with benidipine (0 or 3  $\mu\text{M}$  in 0.3% DMSO) and subjected to TTFields (200 kHz, 1 V/cm) for 5–7 days and further grown for 10–14 days in the continuous presence of benidipine. Thereafter, clusters of  $\geq 50$  cells were defined as colonies and counted manually after fixation and Coomassie

staining. The plating efficiency was defined by dividing the number of colonies by the number of plated cells. Survival fractions were calculated by dividing the plating efficiency of the TTFields-treated cells by those of the TTFields-untreated vehicle controls. Survival fractions were calculated by dividing the plating efficiency of the TTFields-treated cells by those of the TTFields-untreated vehicle controls.

## 2.8. Statistics

Data are given as means  $\pm$  standard error (SE). Probability ( $p$ ) of statistical significance was estimated with two-tailed Student's  $t$ -test. A  $p$ -value of  $\leq 0.05$  (2 samples) or  $\leq 0.05/n$  (2 samples) was assumed to be significant where  $n$  = number of pair wise comparisons in multiple testing (Bonferroni correction).  $n$  = number of pair wise comparisons in multiple testing (Bonferroni correction).

## 3. Results

### 3.1. Results

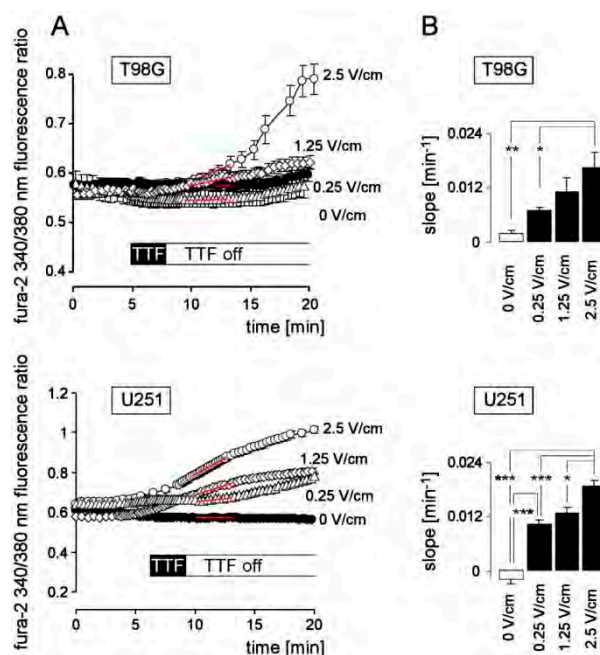

To identify molecular TTFields targets, a TTFields single cell applicator (Figure 1) was constructed. To identify molecular TTFields targets, a TTFields single cell applicator (Figure 1) was constructed, and TTFields single cell applicator. Attached to the stage of an inverted microscope, the TTFields single cell applicator allowed application of electric fields across parallel variable amplitude and frequency to individual cells. TTFields were applied parallel to the plane of the cell layer (active conductive junctions (as applied Ag/AgCl electrodes) is that, in the only difference situation possible, TTFields injection (as applied to the patients) is that bathing solution is not possible. The electrical stimulation may, additionally, in the bathing solution, predominantly of the cells (the solution interface). Total ion exchange is prevented by constant superfusion of the cells that guaranteed fast bath solution exchange. The frequency of 0.25–2.5 V/cm was set to 200 kHz. In the bath solution, the output adjusted to electric field strength of 0.25–2.5 V/cm measured in the bath solution between the two electrodes (Figure 1C).

**Figure 11.** Single cell TTFields applicator. (A) Drawing of the applicator. TTFields are applied conductively by two Ag/AgCl electrodes connected via a capacitance (to avoid flow of offset direct current) to a function generator (37 Hz). (B) Positioning of the TTFields applicator. Petri dish, superfusion insert, heating insert, stage of an inverted microscope. TTFields application and cell recording were performed at 37 °C during continuous superfusion with bath solution. Field strength in the bath solution between both application electrodes at the dish bottom was controlled by the use of two Ag/AgCl recording electrodes. (C) Recorded voltages (peak to peak) within the TTFields at different distances. TTFields field strength was adjusted to 2.5 V/cm (closed triangles) and 1.1 V/cm (open squares) in NaCl solution, respectively. Recorded voltages were fitted by linear regression. The obtained correlation coefficients ( $r^2$ ) were  $r^2 = 0.9541$  and  $r^2 = 0.9866$ , suggesting a homogeneous distribution of the alternating electric fields between the applicator electrodes.

Since low alternating electric fields have been reported to interfere with intracellular  $\text{Ca}^{2+}$  signaling (see Introduction section), we first assessed TTFields-induced changes in intracellular free  $\text{Ca}^{2+}$  concentration ( $[\text{Ca}^{2+}]_{\text{free}}$ ) by ratio-metric fura-2  $\text{Ca}^{2+}$  imaging. As a result, acute application of TTFields to U251 and U937 and glioblastoma cells induced a long-lasting increase in  $[\text{Ca}^{2+}]_{\text{free}}$  in an electric field intensity (0.25–2.5 V/cm)-dependent manner (Figure 2A,B). In particular,  $[\text{Ca}^{2+}]_{\text{free}}$  continued to rise for more than 10 min after switching off the TTFields stimulation.

**Figure 2.** TTFIELDS induce  $\text{Ca}^{2+}$  signals in U251 and T98G human glioblastoma cells in a dose-dependent manner. (A) Time course of mean ( $\pm$  SE;  $n = 8$ –17) fura-2 340/380 nm fluorescence ratio as a measure of  $[\text{Ca}^{2+}]_i$  recorded in T98G (top) and U251 cells (bottom) during superfusion with 1 mM  $\text{Ca}^{2+}$ -containing NaCl-solution before, during and after application of 0 (control), 0.25, 1.25, or 2.5 V/cm TTFIELDS (200 kHz) field strength for 3 min. (B) Mean ( $\pm$  SE;  $n = 8$ –55) slope (as indicated by red lines in (A)) of the TTFIELDS-induced increase in fura-2 340/380 nm fluorescence ratio as calculated for U251 (left) and T98G (right) cells. \*, \*\*, and \*\*\* in (B) indicate  $p < 0.05$ ,  $p < 0.01$ , and  $p < 0.001$ , respectively, (Welch)-corrected t-test and Bonferroni correction for 6 pairwise comparisons.

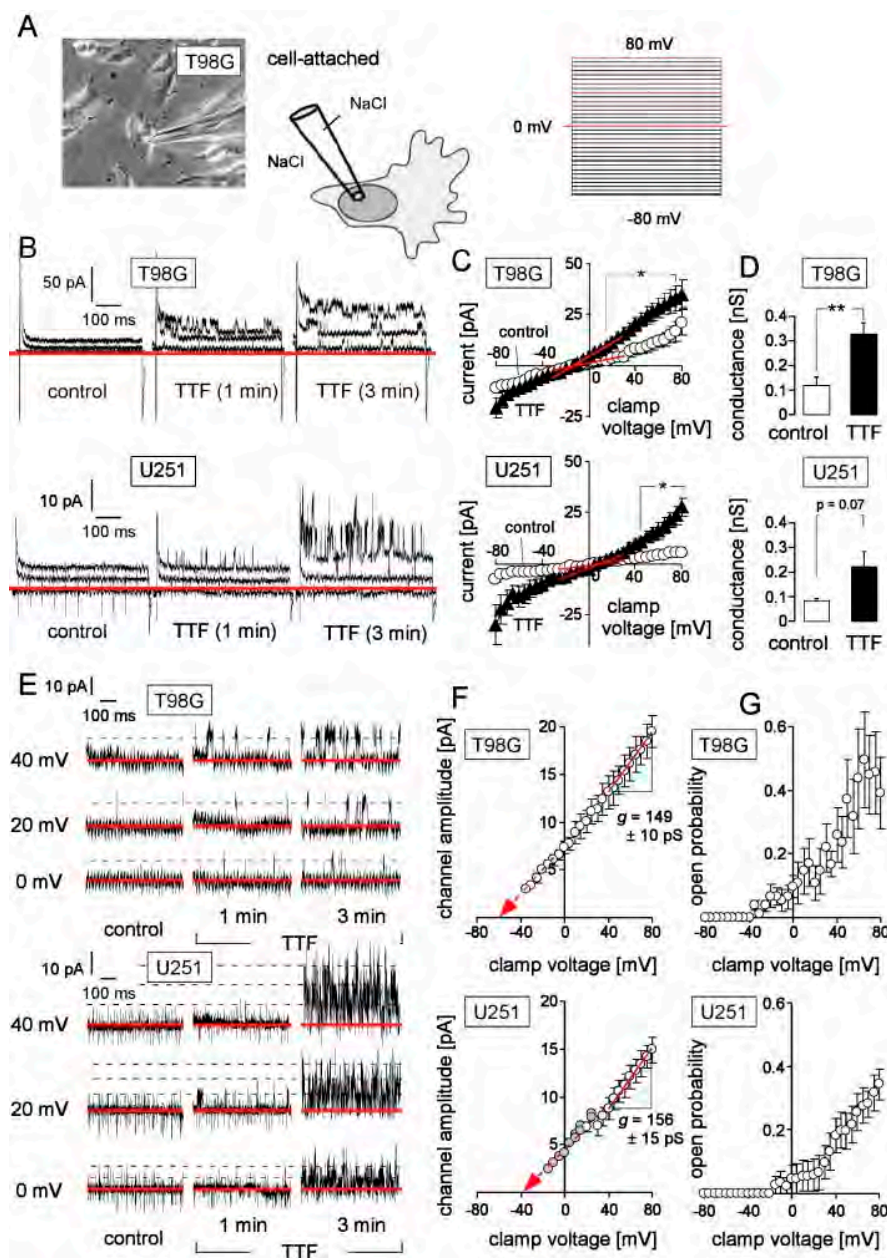

To test for functional significance of this TTFIELDS-induced rise in  $[\text{Ca}^{2+}]_i$ , functionality of  $\text{Ca}^{2+}$ -activated  $\text{K}^+$  channels in the plasma membrane was monitored shortly before and directly after TTFIELDS application (2.5 V/cm for 1–3 min) by continuous cell-attached patch-clamp recording with physiological extracellular NaCl solution in bath and pipette (Figure 3A).

Due to the experimental set-up with an electrical line from the function generator outside the Faraday cage to the TTFIELDS applicator electrodes that were placed closely to the recorded cells inside the Petri dish, a high 50 Hz ripple superimposed the cell-attached currents. This rendered it impossible to resolve unitary current transitions generated by low or intermediate conductance ion channels. However, the “macroscopic” cell-attached currents as a measure of overall channel activity of the channels. However, the “macroscopic” cell-attached currents as a measure of overall channel activity recorded membrane area could be analyzed. As a result, TTFIELDS induced in both glioblastoma lines an instantaneous increase in macroscopic cell-attached outward currents at positive clamp voltages (Figure 3A–C). Moreover, in the range of the physiological membrane potential (i.e., at 0 mV voltage, see below), TTFIELDS increased (T98G cells) or showed a trend to increase (U251) the conductance of the clamped membrane area (Figure 3D) suggesting that TTFIELDS may interfere with the physiological electrosignaling of glioblastoma cells.

Remarkably, the macroscopic currents in Figure 3B (middle, right) disclose large unitary current transitions that could be characterized in more detail (Figure 3E–G). Figure 3E shows in higher power cell-attached current tracings at three clamp voltages (0, +20 and +40 mV) before (left) and after 1 min (middle) or 3 min (right) of TTFIELDS application in T98G (top) and U251 cells (bottom). In both glioblastoma lines, TTFIELDS stimulated the activity of a channel with a conductance in the range of 150 pS as deduced from the channel amplitude/voltage (I/V) relationships in Figure 3F. In addition, the I/V curves in this figure extrapolate (red arrow) to a reversal potential (i.e., where the curve crosses the x-axis) of around -60 mV in T98G cells (Figure 3F, top) and around -40 mV clamp voltage in U251 cells (Figure 3F, bottom). In cell attached mode when recorded with a physiological (i.e., 5 mM  $\text{K}^+$ -containing) NaCl pipette and bath solution, the (negative) physiological membrane

Cancers 2019, 11, 110 voltage in U251 cells (Figure 3F, bottom). In cell attached mode when recorded with a physiological (i.e., 5 mM  $K^+$ -containing) NaCl pipette and bath solution, the (negative) physiological membrane potential remains unaltered and applied on top of the clamp voltage across the recorded membrane. Thus, the actual reversal potentials of the I/V curves in Figure 3F are more negative than those deduced from the clamp voltage. This is important since it suggests that the actual reversal potential of the TTFs-activated channel is close to the highly negative  $K^+$  equilibrium potential indicating its  $K^+$  selectivity.

**Figure 3.** TTFs activate BK  $K^+$  channels. (A) Macroscopic cell-attached currents were recorded from T98G (micrograph on the left) and U251 cells with the patch-clamp technique using a physiological NaCl-rich extracellular solution in bath and pipette (middle). Currents were elicited by 33 square pulses (700 ms each) to voltages between  $-80$  and  $+80$  mV delivered from  $0$  mV holding potential in  $5$  mV increments as shown by the voltage-clamp pulse protocol on the right. (B) Cell-attached current tracings recorded as in (A) from a T98G (top) and a U251 cell (bottom) before (left), after  $1$  min (middle) and  $3$  min (right) TTFs ( $200$  kHz,  $2.5$  V/cm) application. As illustrated by the red lines in the pulse protocol (A right), only currents elicited by voltage steps to  $0$ ,  $+40$  and  $+80$  mV are shown (red lines in (B) indicate the zero current). (C) Relationship between the mean ( $\pm$  SE;  $n = 10$ – $11$ ) macroscopic cell-attached currents and the clamp voltage in control ( $0$  V/cm, open circles) and

5 mV increments as shown by the voltage-clamp pulse protocol on the right. (B) Cell-attached current tracings recorded as in (A) from a T98G (top) and a U251 cell (bottom) before (left), after 1 min (middle) and 3 min (right) TTFields (200 kHz, 2.5 V/cm) application. As illustrated by the red lines in the pulse protocol (A, right), only currents elicited by voltage steps to 0, +40 and +80 mV are shown (red lines in (B) indicate the zero current). (C) Relationship between the mean ( $\pm$ SE;  $n = 10$ –11) macroscopic cell-attached currents and the clamp voltage in control (0 V/cm, open circles) and TTFields (2.5 V/cm)-treated (closed triangles) T98G ( $n = 10$ , top) and U251 cells ( $n = 6$ , bottom). (D) Mean ( $\pm$ SE;) conductance of the clamped membrane area in T98G (top) and U251 cells (bottom) as calculated between  $-30$  and  $+30$  mV clamp voltage from the data in (C, red lines) by linear regression. \* and \*\* in (C, and F, top) indicate  $p \leq 0.05$  and  $p \leq 0.01$ , respectively, Welch-corrected  $t$ -test. The square brackets in (C) mark the voltage range, where control and TTFields-stimulated cell-attached currents differ significantly; the number in (D, bottom) indicates the  $p$  value. (E) Cell-attached current tracings recorded in a T98G (top) and a U251 cell (bottom) at 0, +20 and +40 mV clamp voltage before (control) and after 1 and 3 min of TTFields exposure disclosing TTFields-induced unitary outward current transitions (red lines and dashed lines indicate zero current and distinct current levels of up to three simultaneously open channels, respectively). (E,G) Relationship between channel amplitude (F) and estimated open probability (G) of the unitary current transitions in T98G (top) and U251 cells (bottom). Shown are mean ( $\pm$ SE,  $n = 3$ –5, open symbols) or individual data (grey symbols). The red lines and red arrows in (F) depict the clamp voltage range used to calculate the single channel conductance ( $g$ ) by linear regression and extrapolate to the likely reversal potential, respectively.

An estimation of the open probability ( $P_o$ ) of this high conductance  $K^+$  channel (Figure 3G) further suggests for both glioblastoma lines a depolarization-induced activation of the channel and an increase in its  $P_o$  with increasing positive voltage. Notably, the  $P_o$ /voltage relationship (Figure 3G, bottom) as well as the  $I/V$  curve (Figure 3F, bottom) of U251 cells were shifted by some +20 mV when compared to the situation in T98G cells (Figure 3F,G, top). This can be explained with a higher negative physiological membrane potential in U251 as compared to T98G cells since the higher the physiological membrane potential the more positive clamp voltage is required to reach the activation voltage of the channel. Most importantly,  $K^+$  selectivity, high unitary conductance, and voltage dependence of the TTFields-induced channel were identical to the characteristics of paxilline-sensitive BK  $K^+$  channels reported earlier to be highly expressed in T98G and U251 cells [45].

The  $I/V$  curves in Figure 3C especially in U251 cells also show a trend to TTFields-stimulated inward currents which, however, did not reach statistical significance. The underlying single channel activity could not be resolved because of the above mentioned limitations of our experimental set up. Along those lines, inward current transitions generated by  $Ca^{2+}$  channels such as low conductance voltage-gated L-type channels (e.g., upon depolarization from 0 mV clamp voltage, i.e., from the physiological membrane potential, to +40 mV clamp voltage) could also not be resolved. The same holds true for  $IK_{Ca}$  ( $KCa3.1$ ,  $SK4$ )-mediated outward current transitions. Nevertheless, our observations suggest that the observed TTFields-induced increase in  $free[Ca^{2+}]_i$  is functionally relevant and sufficient to activate BK  $K^+$  channels.

Next, we characterized the TTFields-induced  $free[Ca^{2+}]_i$  rise in further fura-2 experiments by analyzing its dependence on extracellular  $Ca^{2+}$  and its sensitivity to the  $Ca^{2+}$  channel inhibitors benidipine and nifedipine (1  $\mu$ M, both). In both glioblastoma lines, decrease of extracellular  $Ca^{2+}$  by superfusion with  $Ca^{2+}$ -free, EGTA-chelated NaCl solution (Figure 4A) or application of the L-, N-, T-type  $Ca_v$  channel blocker benidipine in  $Ca^{2+}$ -containing superfusate (Figure 4B,C,E) abolished the TTFields-induced rise in  $free[Ca^{2+}]_i$ . In contrast to benidipine, the L-type  $Ca_v$  inhibitor nifedipine abolished only in T98G cells the TTFields-induced  $free[Ca^{2+}]_i$  rise completely while conferring only a partial blockage in U251 cells (Figure 4B,D,E). Notably,  $free[Ca^{2+}]_i$  started to increase for several minutes upon wash-out of benidipine and nifedipine 2 min and 5 min, respectively, after switching off the TTFields stimulation (Figure 4C). Together, those experiments suggest a TTFields-induced  $Ca^{2+}$  entry via the activation of a nifedipine-sensitive L-type  $Ca_v$  channels in T98G and U251 cells and via an

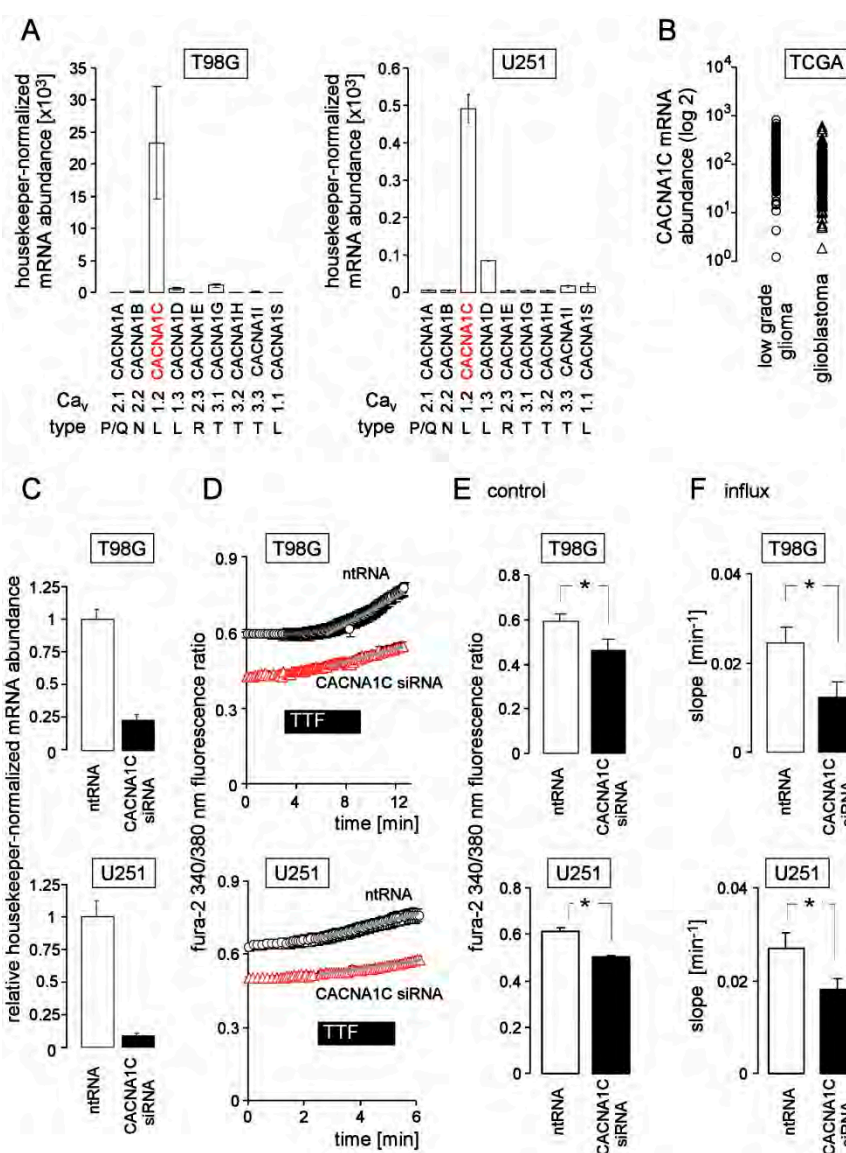

Further on, we analyzed the expression of potential benidipine targets in glioblastoma. To this end, we assessed the abundance of mRNA encoding  $\text{Ca}^{2+}$  channels in our two human glioblastoma cell lines and in glioma resection specimens by RT-PCR and by querying the TCGA low grade glioma and provisional glioblastoma data bases, respectively. Among all tested mRNAs, the mRNA of the L-type channel CACNA1C ( $\text{Ca}_v1.2$ ) was most abundant in T98G and U251 cells (Figure 5A). In T98G, housekeeper-normalized CACNA1C mRNA abundance exceeded that of U251 cells by almost factor of 50. Similarly, CACNA1C mRNA abundance varied considerably in resection specimens of low grade and high grade glioma (Figure 5B). Together, these data suggest CACNA1C is expressed in glioblastoma albeit at variable extent. To test for functional significance of this channel, the effect of CACNA1C knockdown (Figure 5C–F) on control and TTFIELDS-modulated  $\text{free}[\text{Ca}^{2+}]_i$  in T98G and U251 cells was determined by fura-2  $\text{Ca}^{2+}$  imaging. As shown in Figure 5D,E, transfection with CACNA1C siRNA decreased resting  $\text{free}[\text{Ca}^{2+}]_i$  suggesting constitutive activity of  $\text{Ca}_v1.2$  in both cell lines. Moreover, CACNA1C siRNA lowered the slope of the TTFIELDS-induced  $\text{free}[\text{Ca}^{2+}]_i$  rise in T98G and U251 cells (Figure 5D,F) pointing to an involvement of  $\text{Ca}_v1.2$  in here.

**Figure 5.** The voltage-gated L-type  $\text{Ca}^{2+}$  channel CACNA1C ( $\text{Ca}_v1.2$ ) contributes to the TTFIELDS-induced  $\text{Ca}^{2+}$  entry. (A) Mean ( $\pm$  SE;  $n = 3$ ) housekeeper-normalized mRNA abundances ( $\times 10^3$ ) of P/Q-, N-, L-, R- and T-type  $\text{Ca}_v$  channels CACNA1A, -1B, -1C, -1D, -1E, -1G, -1H, -1I, and -1S (as indicated) in T98G (left) and U251 (right) cells as determined by real-time RT-PCR indicating expression of CACNA1C in both human glioblastoma lines. (B) CACNA1C mRNA abundances (log2 RNA seq) of human low grade glioma (left) and glioblastoma (right) specimens vary considerably between individual tumors. The provisional Glioblastoma-Multiforme and Lower-Grade-Glioma TCGA databases (<http://cancergenome.nih.gov/>) were queried for CACNA1C mRNA abundance in the

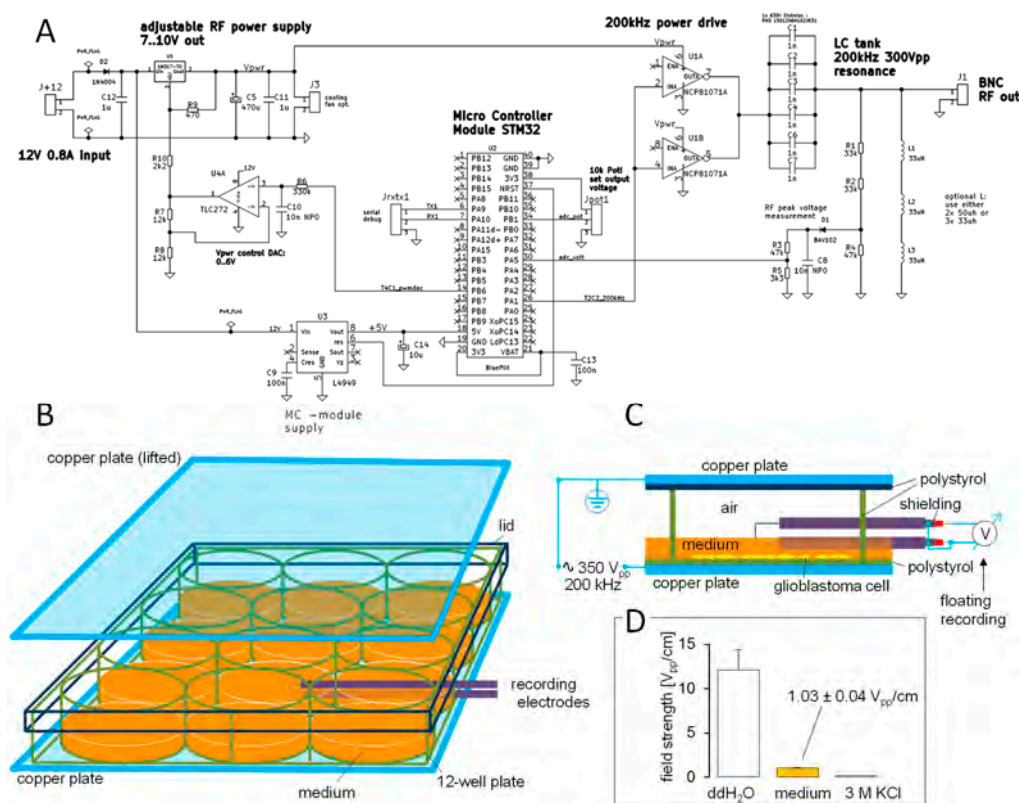

TTFields-induced  $\text{Ca}^{2+}$  entry. (A) Mean ( $\pm$ SE;  $n = 3$ ) housekeeper-normalized mRNA abundances [ $\times 10^3$ ] of P/Q-, N-, L-, R- and T-type  $\text{Ca}_v$  channels CACNA1A, -1B, -1C, -1D, -1E, -1G, -1H, -1I, and -1S (as indicated) in T98G (left) and U251 (right) cells as determined by real-time RT-PCR indicating expression of CACNA1C in both human glioblastoma lines. (B) CACNA1C mRNA abundances (log2 RNA seq data) of human low grade glioma (left) and glioblastoma (right) specimens vary considerably between individual tumors. The provisional Glioblastoma-Multiforme and Lower-Grade-Glioma TCGA databases (<http://cancergenome.nih.gov/>) were queried for CACNA1C mRNA abundance in the tumor specimens via the cBIOportal Web resource [46,47]. (C) Mean ( $\pm$ SE;  $n = 3$ ) relative housekeeper-normalized abundance of CACNA1C mRNA in T98G (top) and U251 (bottom) cells 48 h after reverse transfection with CACNA1C-siRNA (closed bars) or non-targeting RNA (ntRNA, open bars). (D) Mean ( $\pm$ SE;  $n = 6$ –19) fura-2 340/380 nm fluorescence ratio of CACNA1C siRNA (red triangles)- or ntRNA-transfected (open circles) T98G (top) and U251 cells (bottom), before, during and after application of TTFields (200 kHz, 2.5 V/cm, 3–5 min). (E,F) Mean ( $\pm$ SE;  $n = 6$ –19) control ratio (E) and TTFields-induced increase in (F) fluorescence ratio of CACNA1C siRNA (red bars)- or ntRNA-transfected (open bars) T98G (top) and U251 cells (bottom). \* indicates  $p \leq 0.05$ , Welch-corrected  $t$ -test).

To study the interaction of TTFields with cell biology, we developed a cell culture TTFields applicator that applied 200 kHz sine wave electrical fields to a multi-well plate (Figure 6A). The field (1 V/cm peak-to-peak amplitude) was injected perpendicular to the cell layer in a capacitive manner via electrically isolated copper foils mounted below the bottom and above the lid of the multi-well plate (Figure 6B–D). To identify effects of TTFields on cell cycle and the role of  $\text{Ca}_v1.2$  herein, we co-treated T98G and U251 cells for 5–7 days with TTFields (0 or 1 V/cm) and benidipine (0 or 1  $\mu\text{M}$ ) and determined the cellular DNA content by propidium iodide staining in flow cytometry thereafter. In T98G, TTFields showed a tendency to decrease  $G_1$  population and significantly increased S and decreased  $G_2$  populations (Figure 7A top and Figure 7B, upper row) suggestive of a TTFields-induced S phase arrest. Benidipine alone did not affect cell cycle distribution in T98G cells but augmented the TTFields effect on  $G_1$  and S populations (Figure 7A top and Figure 7B, upper row). In contrast, TTFields increased  $G_1$  and decreased  $G_2$  population of U251 cells (Figure 7A bottom and Figure 7B, lower row) indicative of a TTFields induced  $G_1$  arrest. Unlike T98G, benidipine had no effect on cell cycle distribution of U251 cells (Figure 7B, lower row).

To further identify TTFields-caused asymmetric cell division, hyper-G population (i.e., cells with DNA content larger than normal diploid cells) was quantified as a measure of chromosome aneuploidy. In T98G, benidipine tended to elevate and TTFields increased hyper-G population, and both effects seemed to be additive (Figure 7C,D, top each). In U251, by contrast, TTFields tended to decrease hyper-G population while benidipine had no effect (Figure 7C,D, bottom each). Finally, sub- $G_1$  population was analyzed as a measure of dying or dead cells with degraded DNA. In T98G, TTFields and benidipine additively induced cell death (Figure 7E,F, top each). In U251, in contrast, neither TTFields nor benidipine evoked cell death (Figure 7E,F, bottom each).

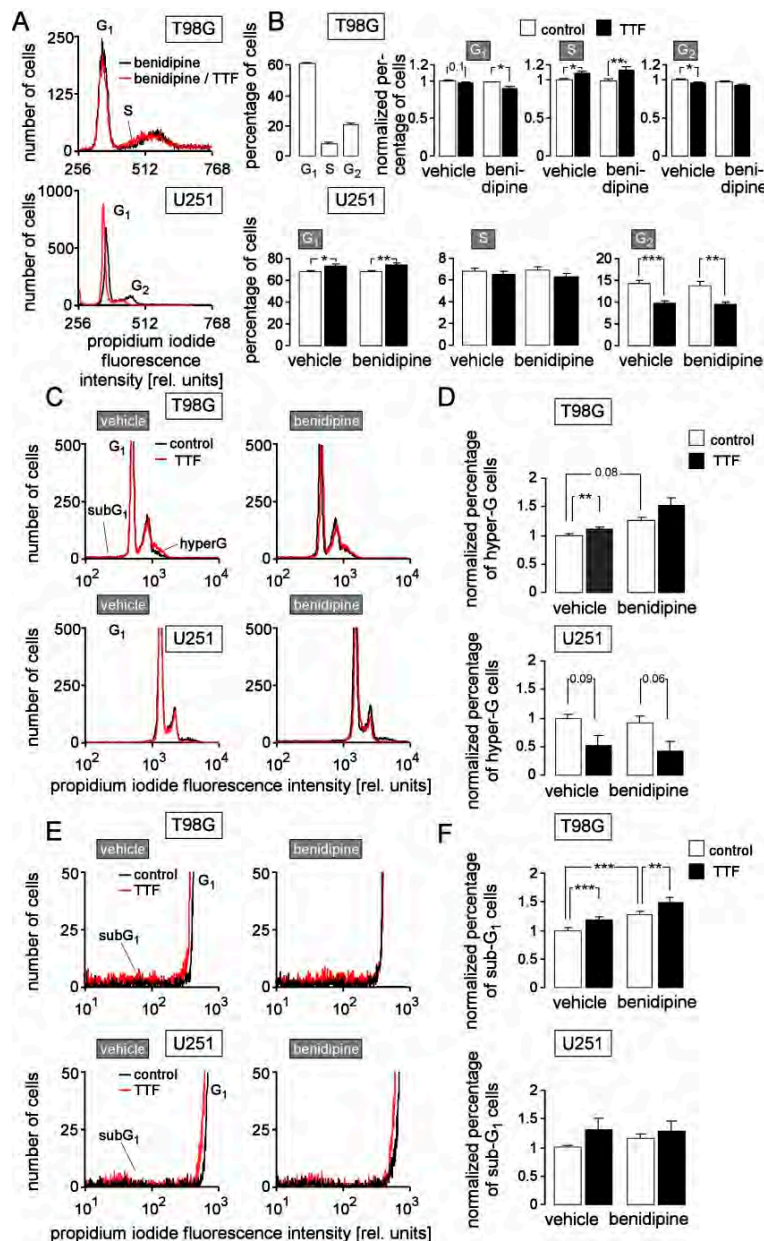

To characterize potential death pathways, we determined the inner mitochondrial membrane potential ( $\Delta\Psi_m$ ) by TMRE staining in flow cytometry in T98G and U251 cells treated with TTFields (0 or 1 V/cm) and benidipine (0 or 1  $\mu\text{M}$ ) using time schedules identical to those applied for cell cycle analysis. In T98G, TTFields showed a trend to induce  $\Delta\Psi_m$  dissipation as indicated by low TMRE staining while benidipine alone had no effect. In combination, however, TTFields and benidipine evoked a doubling of cell population with dissipated  $\Delta\Psi_m$  suggesting their synergistic action (Figure 8A,B top each). In U251, in contrast, TTFields and benidipine in each case alone stimulated  $\Delta\Psi_m$  dissipation (3-fold and 1.5-fold, respectively), effects that were not additive in combined treatment (Figure 8A,B bottom each). Together, these data suggest that TTFields alone (U251) or in combination with benidipine (T98G) may trigger intrinsic apoptosis.

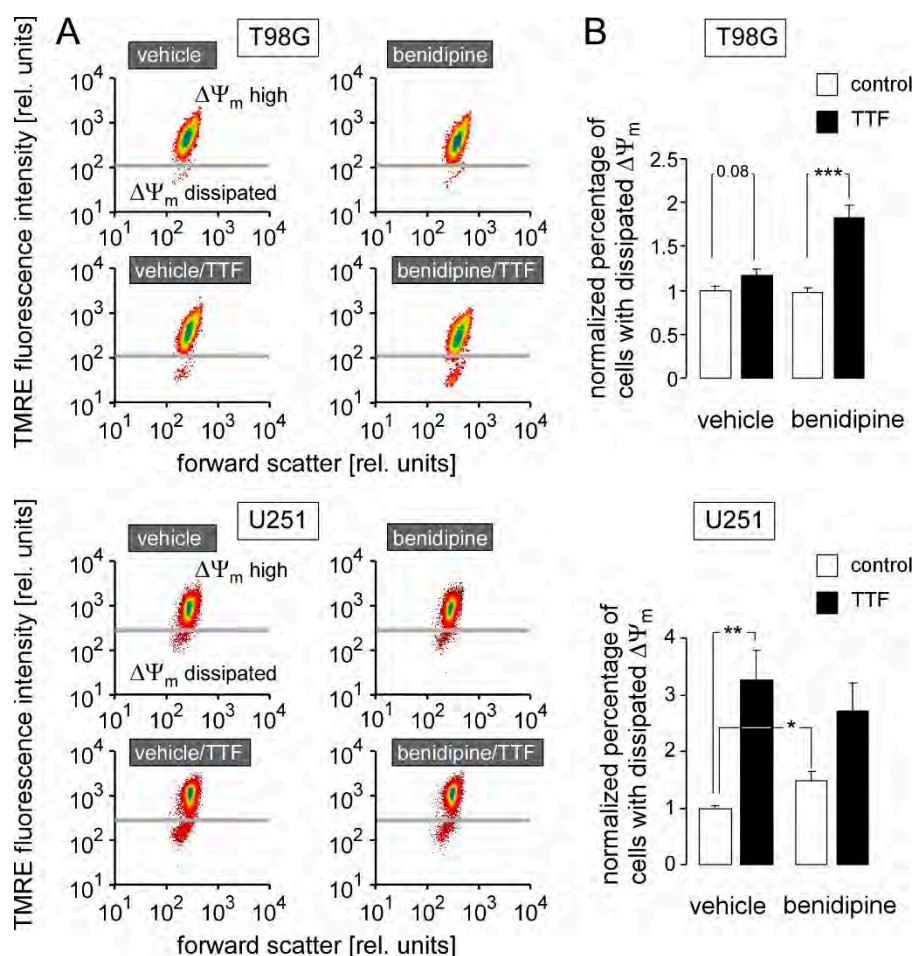

**Figure 6.** Cell culture TFields applicator. (A) Circuitry of applicator. Frequency and amplitude of the 200 kHz, 300 Vpp TFields signal is controlled by a “STM32 blue pill” micro controller module (MCM). Software was developed with the free ARDUINO programming environment. A 200 kHz digital clock is generated by the MCM internal programmable timers. This clock is amplified by a stage that delivers sufficient current and voltage to drive a 200 kHz series LC resonance tank. LC power drive stage that delivers sufficient current and voltage to drive a 200 kHz series LC resonance tank. LC tank resonance transforms the digital 7 to 10 V peak to peak drive signal into a clean sine wave of 200 kHz and up to 350 V peak to peak at the RF output. Amplitude can be set by a potentiometer which controls the supply voltage of the LC-tank power drive. (B–D) Calibration of the applicator. TFields (maximal output) are applied capacitively via two electrically isolated copper foils mounted below and above a 12-well cell culture plate. The electric field strength applying to the cells was determined under the chosen experimental conditions by the use of two shielded electrodes that were inserted laterally in a central well of a 12-well plate measuring chamber filled with 1 ml culture medium in that were inserted laterally in a central well of a 12-well plate measuring chamber filled with 1 ml every well (B,C). For quality control of this measurement, the culture medium of the recorded well was replaced by media with lower (ddH<sub>2</sub>O) and higher (3 M KCl) dielectric constant. As a result, electric field strength (maximal output) in cell culture medium was the range of 1 V/cm. Moreover, decreasing (ddH<sub>2</sub>O) or increasing the permittivity (3 M KCl) increased and decreased, respectively, the electric field strength accordingly (D, data are means ± SE, n = 3–4). In particular, electric field strength in respectively, the electric field strength accordingly (D, data are means ± SE, n = 3–4). In particular, ddH<sub>2</sub>O was about 12-times that of plasma-isotone cell culture medium (D) which suggests a relative dielectric constant of around 1000 for the cell culture medium similar to the value reported for human plasma in this wavelength range [48]. The TFields application (5–7 days) was performed in a normal humidified 37 °C cell culture incubator in 5% CO<sub>2</sub> atmosphere. Continuous TFields application did not increase the temperature of the cultured cells. Temperature recording during up to 24 h of TFields (maximal output) with a thermo-resistor directly placed in the fluid column of the cell-culture well did not disclose any TFields-associated temperature increase (36.4 ± 0.17 °C, n = 5) as compared to control recording in the same set-up with switched-off TFields (36.5 ± 0.07 °C, n = 3).

**Figure 7.** TTF field stimulation at G<sub>1</sub> or G<sub>2</sub> cell cycle arrest in T98G and U251 cells and an increase in hyper-G and sub-G<sub>1</sub> populations at T98G. T98G cells (top) and U251 cells (bottom) treated for 7 days with TTF fields of 0 (black) or 1 V/cm (red) field strength and benidipine (0 or 1  $\mu$ M). (A,C,E) Histograms of flow cytometry showing the DNA content (DNA content with propidium iodide staining) in T98G (top) and U251 (bottom) cells. (B,D,F) Bar graphs showing the percentage of cells in G<sub>1</sub>, S, or G<sub>2</sub> phase of cell cycle (B, upper line, 2nd to 4th bar diagram and lower line, the bar diagram in the upper left gives the absolute values for the control situation in T98G), cells with elevated DNA content (hyper-G population, D), absolute values in the control situation were  $7.0 \pm 0.6\%$  for T98G and  $3.9 \pm 0.5\%$  for U251, and dead cells (sub-G<sub>1</sub> population, F), absolute values in the control situation were  $2.8 \pm 0.3\%$  for T98G and  $0.4\%$  for U251. (E) absolute values in the control situation were  $2.8 \pm 0.3\%$  for T98G and  $0.4\%$  for U251. (F) absolute values in the control situation were  $2.8 \pm 0.3\%$  for T98G and  $0.4\%$  for U251. (B, upper line, 2nd diagram) and (D) indicate  $p$  values.

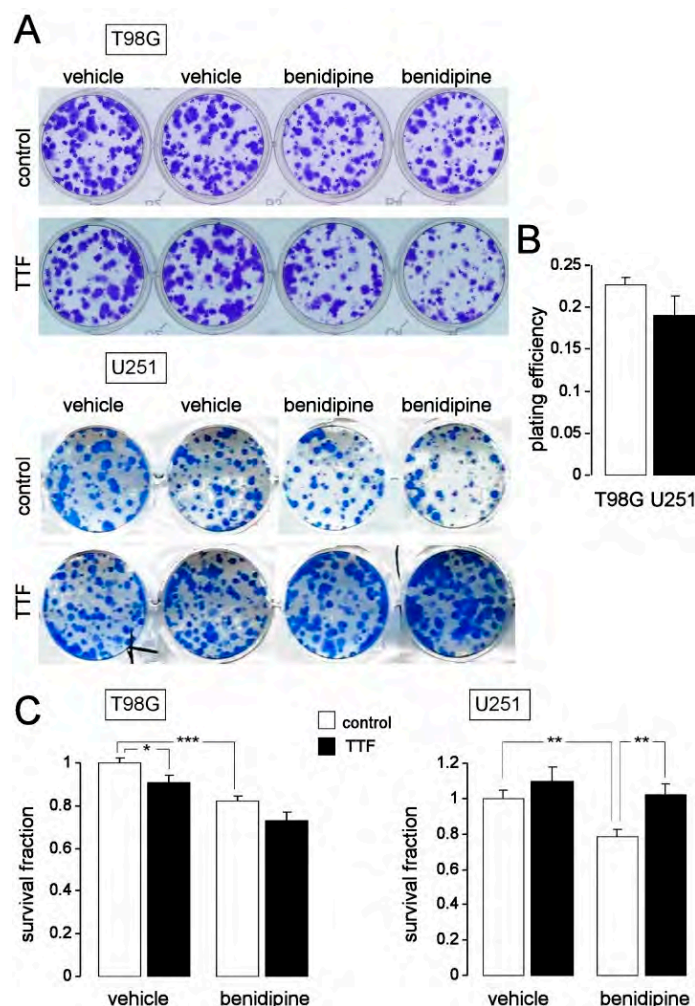

**Figure 8.** Benidipine augments TTFIELDS-induced breakdown of the inner mitochondrial membrane potential ( $\Delta\Psi_m$ ) in T98G cells. (A) Dot plots showing forward scatter and TMRE fluorescence intensity of T98G (top) and U251 cells (bottom) treated for 7 days with 0 (control) or 2.5 V/cm TTFIELDS (200 kHz) in the absence (vehicle) or presence of benidipine (1  $\mu$ M). (B) Mean ( $\pm$  SE;  $n=12-22$ ) normalized percentage of T98G (top) and U251 (bottom) cells with dissipated  $\Delta\Psi_m$  after 5–7 days of treatment with 0 (control) or 1 V/cm TTFIELDS (TTF, 200 kHz) and 0 or 1  $\mu$ M benidipine (absolute values of the control situation were  $4.5 \pm 1.0\%$  for T98G and  $4.3 \pm 1.3\%$  for U251). \*, \*\*, and \*\*\* indicate  $p \leq 0.05$  and  $p \leq 0.01$ , respectively, Welch-corrected *t*-test and Bonferroni correction for three pairwise comparisons (vehicle/control vs. benidipine/control, vehicle/control vs. vehicle/control + TTFIELDS, and benidipine/control vs. benidipine/TTFIELDS). Number in (B, top) indicates *p* value.

Finally, we defined whether or not TTFIELDS-induced cell death may lower clonogenic survival which is the most relevant endpoint in oncology with regard to tumor relapse after therapy. Pre-plating colony formation assay (5–7 days of TTFIELDS with 0 or 1 V/cm and co-incubation with 0 or 3  $\mu$ M benidipine followed by 10–14 days of post-incubation in the continuous presence of benidipine until formation of colonies, Figure 9A,B) suggest that both, TTFIELDS- and benidipine monotherapies, attenuated clonogenic survival of T98G cells. In combination, the effects of both therapies tended to be additive (Figure 9A, top and Figure 9C, left). In U251, in sharp contrast, TTFIELDS rather increased clonogenic survival and abolished the inhibitory effect of benidipine (Figure 9A, bottom and Figure 9C, right). In summary, our experiments suggest that TTFIELDS modulate  $Ca^{2+}$  signaling in two human glioblastoma cell lines which involves long-lasting activation of L-type  $Ca_v1.2$  (CACNA1C) and most probably further  $Ca_v$  channels and which was completely suppressed by  $Ca^{2+}$  channel inhibitor benidipine. Cell line-dependently, TTFIELDS induce S (T98G) or G<sub>1</sub> cell cycle arrest (U251), aneuploidy, and DNA degradation (T98G), triggered intrinsic apoptosis (U251), and decreased clonogenic survival

(T98G). Importantly, in T98G cells which exhibited about 50 times higher CACNA1C mRNA abundance than U251, but not in U251 cells, benidipine aggravated TTFields-triggered cell cycle arrest, intrinsic apoptosis and DNA degradation and showed a tendency to act additively to TTFields on induction of aneuploidy and attenuation of clonogenic survival. In U251, benidipine alone triggered intrinsic apoptosis and decreased clonogenic survival. The latter was reversed by TTFields.

**Figure 9.** TTFields reduce clonogenic survival of T98G but not of U251 cells. (A) Pre-plating colony formation of T98G (top) and U251 (bottom) cells after treatment with 0 V/m (control) or 1 V/m TTFields field strength and co-incubation with vehicle alone or benidipine (1 µM) for 7 days. Shown are cut-outs of 6-well plates with Coomassie-stained T98G (top) and U251 (bottom) colonies. (B) Mean (±SE,  $n = 16-22$ ) plating efficiency of T98G and U251 cells. (C) Mean (±SE,  $n = 16-24$ ) survival fractions of T98G (left) and U251 cells (right) after treatment with 0 V/m (control) or 1 V/m TTFields strength and co-incubation with vehicle alone or benidipine (3 µM) for 7 days. Data were obtained by pre-plating colony formation assay as shown in (A). \* and \*\* indicate  $3p \leq 0.05$ ,  $3p \leq 0.01$ , and  $3p \leq 0.001$ , respectively. Welch-corrected  $t$ -test and Bonferroni correction for three pairwise comparisons (vehicle/control vs. benidipine/control, vehicle/control vs. vehicle/TTFs, and benidipine/control vs. benidipine/TTFs).

#### 4. Discussion

In our study, TTFields impaired clonogenicity of T98G but not of U251 human glioblastoma cells indicating that individual glioblastoma may respond differentially to this electric field therapy. The inhibition of clonogenic survival of T98G cells by 5–7 days of TTFields was below 10%. At a first glance, this effect seems to be too low to become tumor biologically relevant. However, one has to take into account that field direction (perpendicular and not parallel to the cell layer and field strength (1 V/cm instead of 3 V/cm) did not match the reported [4] optimal settings due to technical limitations of our set-up. This might hint to an underestimation of the TTFields effect by our experiments. In addition, overall treatment time of several months might lead to significantly larger effects on

take into account that field direction (perpendicular and not parallel to the cell layer and field strength (1 V/cm instead of 3 V/cm) did not match the reported [4] optimal settings due to technical limitations of our set-up. This might hint to an underestimation of the TTFields effect by our experiments. In addition, overall treatment time of several months might lead to significantly larger effects on glioblastoma cell death and clonogenic regrowth compared to the one week application of TTFields for our in vitro experiments.

The 6-years follow up of the multicentric randomized prospective clinical trial analyzing temozolomide vs. temozolomide plus TTFields maintenance therapy suggests that in particular glioblastoma patients with methylated MGMT (O-6-methylguanine-DNA methyltransferase) promotor in the tumor benefit from TTFields therapy [2]. This might suggest that efficacy of TTFields increases with decrease of MGMT activity. In our experiments, however, the TTFields more responding line T98G has been reported to express higher MGMT activity [49] than the low TTFields responder U251 [50]. Alternatively, one might speculate that TTFields which is applied concurrently to temozolomide maintenance therapy becomes especially effective in MGMT promotor-methylated, temozolomide-sensitive cells pre-damaged by the chemotherapy. As a matter of fact, temozolomide and TTFields have been reported to synergistically accelerate cell death of irradiated glioblastoma cells in vitro, however, independently of MGMT status [51]. Additive anti-proliferative effects of temozolomide and TTFields have also been reported for temozolomide-sensitive and resistant glioblastoma stem cell-enriched primary cultures [52]. Along those lines, TTFields have been shown in vitro to improve the efficacy of radiotherapy in glioblastoma [23] and non small cell lung cancer cells [14] possibly by impairing repair of DNA double strand breaks [14]. Combined, this might suggest that TTFields are especially efficient in combination with other cytotoxic anti-cancer therapies such as radiotherapy or chemotherapy and enhance their effect as has been described for moderate locoregional hyperthermia [53]. As a matter of fact, combining mitotic checkpoint inhibition with TTFields in vitro synergistically enhance apoptotic cell death in glioblastoma cells [54].

The reported interference with DNA repair by TTFields [14] also suggests that TTFields exert additional cellular effects beyond impairment of mitotic spindle formation and cytokinesis as proposed cellular mechanisms of anti-neoplastic TTFields action (see Section 1). Evidence for the latter two came in our study from the TTFields-induced increase in T98G cell population with hyper-G DNA content as a measure of aneuploidy. Beyond that, our study identified benidipine-sensitive  $\text{Ca}^{2+}$  channels that comprise L-type CACNA1C ( $\text{Ca}_v1.2$ ) channels as further TTFields targets. The dihydropyridine calcium channel blocker benidipine acts on L-, T-, and N-type channels. Like in the present study, alternating current electromagnetic fields (ac-EMF) such as microwave or Wi-Fi have been demonstrated in several independent studies to activate  $\text{Ca}^{2+}$  entry pathway in various cell types. Notably, these pathways were in part sensitive to inhibitors of voltage-gated  $\text{Ca}^{2+}$  channels suggesting that the ac-EMF sensitivity of voltage-gated  $\text{Ca}^{2+}$  channels is a general phenomenon (for review see [33]). Particularly striking was the fact that in our experiments  $\text{Ca}_v$ -mediated  $\text{Ca}^{2+}$  influx outlasted TTFields stimulation by far suggesting a constitutive activity of  $\text{Ca}_v$  channels. As a matter of fact, such constitutive activity has been reported in smooth muscle cells for L-type  $\text{Ca}^{2+}$ -channels. This constitutive activity and functional clustering of channels reportedly are mediated by protein kinase C (PKC) and determine the resting  $_{\text{free}}[\text{Ca}^{2+}]_i$  in these cells [55]. Along those lines, pulsed electrical field induced contraction of feline esophageal smooth muscle cells reportedly requires both, extracellular  $\text{Ca}^{2+}$  and PKC activity [56]. This might suggest that similar processes contribute to the long-lasting  $\text{Ca}^{2+}$  entry in TTFields-treated glioblastoma cells.

Taking into account that cell cycle [57], cell migration [38,45,57], brain infiltration [40], cell death programming [57], DNA repair and radioresistance [42,57] of glioblastoma cells have been demonstrated to be regulated by  $\text{Ca}^{2+}$ -dependent signaling pathways [58] an interference of TTFields with glioblastoma biology can be expected. In line with this assumption, the present study demonstrated that TTFields indeed interfered with all cell biological parameters tested.

Of note, the voltage-gated  $\text{Ca}^{2+}$  channel blocker benidipine did not revert the observed cellular TTFields effects indicating that these effects most probably were not induced by TTFields-triggered benidipine-sensitive  $\text{Ca}^{2+}$  influx. Rather, benidipine aggravated (or showed the tendency to increase) the TTFields effects in T98G cells. Unexpectedly, such a concerted action of benidipine and TTFields was not observed in U251 cells although both glioblastoma lines exhibited comparable TTFields-induced  $\text{Ca}^{2+}$  entries that were both completely blocked by benidipine (see Figure 4). In contrast to T98G, TTFields decreased aneuploidy and rather increased than decreased clonogenic survival in U251 again illustrating that individual glioblastomas may respond differentially to TTFields.

Irrespective of its effect in combination with TTFields, benidipine alone induced in the present study in both glioblastoma lines either DNA degradation (T98G) or  $\Delta\Psi_m$  dissipation (U251) and lowered clonogenic survival (both lines) indicating its anti-neoplastic action. Among the known benidipine targets, mRNA encoding the L-type  $\text{Ca}^{2+}$  channel CACNA1C ( $\text{Ca}_v1.2$ ) was most abundant in both glioblastoma lines strongly suggesting that the observed benidipine effects were mediated at least in part via inhibition of CACNA1C. The functional significance of CACNA1C for the  $\text{Ca}^{2+}$  signaling of both glioblastoma cell lines can be deduced from the decline in resting  $\text{Ca}^{2+}$  concentration (i.e., control  $_{\text{free}}[\text{Ca}^{2+}]_i$ , see Figure 5E) upon knockdown of CACNA1C.

The notion of a presumable general anti-neoplastic function of benidipine in glioblastoma in concert with the observed TTFields stimulation of a benidipine-sensitive target that probably counteract the TTFields effects (at least in the TTFields more responding glioblastoma cell line T98G) provides a rationale to combine alternating electric field therapy with  $\text{Ca}^{2+}$  antagonists even in tumors with unknown TTFields responsiveness. Benidipine, which is in clinical use in Japan and India (Coniel®; Kyowa Hakko Kirin Co., Ltd., Tokyo, Japan [59]) as anti-hypertensive drug is well tolerated. Tissue distribution in rats of orally applied benidipine indicates drug accumulation predominantly in digestive organs, mesenteric lymph nodes, liver, pancreas, urinary bladder, fat tissue, kidney and spleen [60]. The usually high penetrability of the glioblastoma blood barrier is expected to facilitate delivery of benidipine specifically to the glioblastoma while the blood brain barrier can be assumed to hamper distribution of benidipine in healthy brain parenchyma. Combined, this suggests that targeting of glioblastoma  $\text{Ca}^{2+}$  channels by benidipine or other FDA-approved  $\text{Ca}^{2+}$ -antagonists such as nifedipine [61] seems to be clinically feasible.

## 5. Conclusions

TTFields act on several molecular targets/pathways thereby influencing  $\text{Ca}^{2+}$ - and electrosignaling, cell cycle progression, programmed cell death, and clonogenic survival of glioblastoma cells. Concerning the most relevant parameter in oncology that is the clonogenic survival, TTFields responsiveness differed markedly between the two human glioblastoma lines tested suggesting that also in the clinical situation the benefit of TTFields therapy may vary considerably between individual glioblastoma patients. Knowledge of the underlying molecular mechanisms might be used for therapy stratification in the future or for pharmacological intervention and improvement of the tumoricidal TTFields effects. One such potential approach evolves from the present study that disclosed that  $\text{Ca}_v$  channel activity contributes to cellular stress response to TTFields and  $\text{Ca}_v$  inhibition may augment the TTFields effects.

## Abstract

**Background** Tumor treating fields (TTFields) significantly prolong both progression-free and overall survival in patients with newly diagnosed glioblastoma (GBM). TTFields are delivered to the brain tumor via skin transducer arrays and should be applied for a minimum of 18 h per day ( $\geq 75\%$  compliance). This may cause limited acceptance by patients because of obstacles in daily routine. So far, there are limited data on factors influencing therapy acceptance and compliance.

**Methods** In this retrospective study, forty-one patients with primary GBM or recurrent high grade glioma (rHGG) have been treated with TTFields in our department. Compliance reports were generated at the monthly routine check of the device. We investigated demographic data, stage of disease and therapy duration in regard to treatment compliance.

**Results** Thirty percent of patients with primary diagnosis of GBM were informed about TTFields. Acceptance rate among these patients was 36%. In this study, TTFields were prescribed in newly diagnosed GBM patients (57%) and in rHGG. Mean treatment compliance was 87% in the total population independent of age, sex and stage of disease. Compliance was not negatively correlated with time on treatment.

**Conclusion** TTFields are effective in newly diagnosed GBM, therefore acceptance and compliance is important for GBM treatment. We experienced moderate acceptance rate for TTFields, which is influenced by factors such as social support, comorbidities and independence in daily life. Overall therapy compliance lies above 75% and is not influenced by age, sex, stage of disease or duration of therapy. Improved patient consultation strategies will increase acceptance and compliance for better outcome.

**Keywords** Glioblastoma · TTFields treatment · OPTUNE® · Acceptance · Compliance

## Introduction

Standard of care in glioblastoma (GBM) treatment modalities consist of microsurgical resection, radiotherapy and chemotherapy [1]. However, GBM carries a dismal prognosis despite maximum treatment. Recurrence therapy includes re-resection, re-irradiation and recurrence chemotherapy, e.g. temozolomide (TMZ) rechallenge, nitrosurea, bevacizumab [2]. New investigative therapies include immune therapies, e.g. vaccine therapy, oncolytic viruses, checkpoint inhibition etc. [3]. However, recurrence therapy

is less standardized and is often based on caregiver's own experience and beliefs.

One new approach to improve tumor control in GBM is tumor treating fields treatment (TTFields, OPTUNE®, Novocure Ltd.) [4]. Alternating electric fields of low intensity (1–3 V/cm) and intermediate frequency (200 kHz for GBM) are delivered to supratentorial regions of the brain. Four transducer arrays applied to the shaved scalp (two in antero–posterior and 2 in coronal axes) deliver TTFields that target dividing tumor cells, which lead to mitotic catastrophe, autophagy and tumor cell apoptosis [5].

TTFields were introduced as salvage therapy in recurrent GBM. In the EF-11 study therapy proved to be equally effective to best physicians choice chemotherapy when TTFields were used as a monotherapy, despite not improving overall survival. EF-14 study showed that TTFields in patients with newly diagnosed GBM significantly prolonged both progression-free survival and overall survival (OS) by 2.7 and

<sup>2</sup> Berlin School of Integrative Oncology (BSIO), Berlin, Germany

4.9 months, respectively [6], the use of TTFields is viewed with controversy among the neuro-oncological community based on the need for patients to stay at least 75% of time on therapy. Factors to consider for patients when deciding for TTFields are: necessity of hair shaving, frequent array change every 3–4 days, weight of device and spare batteries, visibility of the arrays, increased sweat rate in warm air temperature, alarm tone of the device and orthopedic problems carrying the device. These factors have to be outweighed by gaining increased tumor control and might negatively influence acceptance and compliance towards TTFields. In fact, no systematic data about factors influencing therapy acceptance and compliance exist. With this study we aim to investigate the acceptance of TTFields among high-grade glioma patients and factors contributing to therapy compliance.

## Materials and methods

### Patient cohort

In this retrospective study, we have analyzed data from 175 patients, who have been operated on a primary GBM. Histological diagnosis was confirmed by a neuropathologist. Each patient was presented at consensus conference. 73% of newly diagnosed GBM patients received adjuvant treatment in our institution. Treatment algorithm for newly diagnosed GBM patients in our department is as follows: patients younger than 70 years and in good clinical condition (KPS 70% and better) will be considered for Stupp protocol. Elderly patients (older than 70 years) with KPS 70% and better will be informed about treatment options according to Nordic trial, Perry scheme or Methvsalem study (NOA-08) [7–10]. Elderly patients harboring MGMT promotor methylation were offered temozolomide monotherapy. Table 1 displays detailed patients' characteristics of all GBM patients treated between May 2015 and February 2017 in our institution (primary therapy and tumor recurrence patients). In the same time period all recurrence patients presenting in our neurosurgical outpatient clinic were also screened for possible additional TTFields.

In May 2015, our department became a certified center for TTFields. From that time point on we adopted inclusion and exclusion criteria of EF-14 trial (clinicaltrials.gov Identifier: NCT00916409) for primary GBM therapy [11]. The following patients were considered candidates for TTFields: 18–70 years of age, KPS  $\geq$  70, life expectancy at least 3 months, supra-tentorial tumor and existing social support, e.g. another person who was able and willing to help with hair shaving and frequent array change. Patients with comorbidities like dementia, severe cognitive dysfunction, depression and severe aphasia were not considered eligible for TTFields, because one has to

assume that the patients cannot adequately handle and communicate discomfort about the therapy or technical problems and side effects.

For GBM recurrence, the same criteria had to be met to be offered TTFields as an add-on treatment to recurrence chemotherapy. However, due to the low level of evidence for recurrence therapy and after the publication of the EF-14 data we later decided to offer TTFields almost exclusively for primary treatment.

Hospital charts, medical reports and protocols of consensus conference were screened to identify patients to whom and when TTFields were offered and to identify factors influencing therapy acceptance among patients. Therapy compliance of patients under TTFields was assessed with the monthly gathered electronic records of the device. Here the average daily usage is recorded and the overall compliance for the period is calculated.

### Algorithm for TTFields introduction to GBM patients

We informed GBM patients in our neurosurgical department in a staged approach about TTFields. In case of initial diagnosis of GBM, the malignant diagnosis was communicated to the patient after surgery when we received histopathological diagnosis. As a first step, we explained the malignant nature of the disease and the need for adjuvant treatment. Patients were then introduced to concomitant therapy in the setting of a neuro-oncological outpatient clinic run by neurosurgeons. Here, neurosurgeons informed patients about the possibility of an additional treatment with TTFields (2nd step). We demonstrated the OPTUNE® device and handed out information material provided by Novocure. At the next appointment we discussed questions and concerns regarding TTFields and provided our interpretation of Phase 3 study results (3rd step). Prior to the publication of interim survival data of the EF-14 trial, we informed patients about the potential benefit of adding TTFields to standard therapy according to the interim analysis results and that clinical trial options in our institution would not interfere with TTFields. At that time point, no clinical studies were offered that had TTFields as exclusion criteria. We repeatedly informed patients about the logistics of the therapy including size and weight of the device (1.3 kg), rate of array change, battery life expectancy and the need of a care-giver in the patients' family or social circle for help in applying the arrays (social support). We informed patients about an adjusting phase of up to 4 weeks when patient and caregivers get familiar with the everyday challenges of the therapy. We also prepared the patient in advance about possible obstacles, e.g. skin reactions, and handling of the medical device. In the setting of recurrent disease, we offered TTFields as an additional therapeutic modality after re-irradiation, re-resection or

concurrent to chemotherapy re-challenge. During a period of 20 months, 41 patients decided and started TTFields at different stages of disease.

Once a patient opted for TTFields, they were then introduced by device support specialists to the logistics of therapy at home. NovoTAL (Novocure, Isreal) software was used

to calculate array placement based on the recent MRI [12]. Only patients who had supratentorial lesions were included in our study. The device support specialists generated compliance reports at least monthly and returned these to the prescribing physician. Compliance reports contain data about the average daily usage of the device and the overall compliance for the treatment period. MRI scans were done every 3 months to assess RANO criteria [13]. Patients gave their written informed consent to therapy. Ethics committee approval was obtained for publication of these data.

## Statistics

Statistical analysis was performed using GraphPad Prism 5 (GraphPad Software, La Jolla, CA, USA) and SPSS. Therapy compliance was measured as time on treatment per day and given in percent  $\pm$  standard deviation. 95% confidence interval (95% CI) were given, significance level was set at  $p < 0.05$ . Correlation tests were calculated with the Pearson test. Independent measures of two groups were performed with the Student's *t* test (therapy compliance, gender and stage of disease), independent measures of more than two groups with one-way ANOVA Bonferroni multicomparison test (therapy compliance, KPS and age groups). For non-parametric data, summary data was given as means, median and range.

## Results

### Characteristics of patients receiving TTFields treatment

Between June 2015 and February 2017, 41 patients accepted and started TTFields. Of these, 21 patients (54%) received primary therapy for GBM, 19 patients (46%) had recurrent disease, one patient harbored optic pathway glioma that was not classified as GBM. Fourteen patients were in first recurrence, three patients in second and two in third recurrence. The gender distribution among TTFields users was 16 females to 25 males (1:1.56). Mean age was 47.9 years (median 51 years, range 25–70). Mean KPS at therapy start was 83% (median 80%, range 50–100%) in newly diagnosed GBM and 78% in recurrent GBM (median 80%, range 60–100%). In seven patients KPS at therapy start was not assessed. Twenty-nine patients had IDH-wildtype glioma, seven tumors showed an IDH-mutation, and in five patients IDH-status was unknown. Fourteen patients showed methylation of the MGMT-promotor, while 22 tumors were unmethylated. Four tumors had unknown promotor methylation status. Detailed patients characteristics are shown in Table 2.

### Acceptance of TTFields parallel to first line therapy in GBM patients

TTFields were discussed as an additional therapeutic modality in combination to first line therapy in 58 (33%) out of 175 patients with initial diagnosis of a GBM (Fig. 1). Physicians decided against TTFields based on the

**Fig. 1** Number of TTFields considerations, rejections and assignments among patients with newly diagnosed glioblastoma (GBM) (a) and recurrent GBM (b)

following criteria: age > 70 years, not eligible for standard first line therapy (Stupp treatment), poor KPS (mostly less than 70%) and confounding comorbidities (mental disability including disorientation, dementia, severe memory problems, severe sensory aphasia, depression, neurological deficits like hemiparesis higher than grade 3 and if patients were non-ambulatory) in 57%, residence (e.g. residence in foreign country that kept patients from picking up disposable materials for TTFields) in 18%, lack of social/family support (14%), tumor localization not eligible due to infratentorial tumor expansion (7%).

TTFields were introduced to 58 patients with a new diagnosis of GBM according to the displayed algorithm. Of these, 37 patients decided against TTFields in addition to standard first line therapy, and 21 patients agreed to and started TTFields. Patients' arguments against TTFields were personal: head shaving, visibility of the device, impairment of mobility, independence in daily life, non-compatibility with work (50%), lack of social/family support (17%), technical challenges (8%) and unknown (25%). TTFields was offered to recurrence patients in good clinical condition who actively asked for therapy or inquired about therapies aside from a classical recurrence pattern of therapy only. These patients were mostly younger patients who wanted to do "everything possible" to prolong survival. 58 of 96 recurrence patients were classified eligible for TTFields (60.4%), in these patients acceptance rate was 19 out of 58 patients (32.8%). Overall, 19/96 patients received TTFields in the recurrence situation (19.8%).

### Therapy compliance in patients with newly diagnosed and recurrent GBM

Mean treatment duration was  $5.4 \pm 3.6$  months in all patients (7.2 months in primary therapy versus 4.3 months in recurrent disease). Treatment duration is not reflecting survival rates or progression-free time. Break or termination of TTFields was related to tumor progression followed by re-irradiation or re-resection or worsening of KPS etc. The efficacy of TTFields is optimal at treatment duration of more than 18 h per day, which corresponds to 75% or above compliance over treatment time. Among the investigated patients, the mean compliance was 86% per month (median 90, range 40–98%, Fig. 2). Only four patients stayed below the recommended 75% threshold on therapy within the first month under TTFields. Of these patients, two aborted therapy due to side effects (n = 1 worsening of pre-existing

**Fig. 2** Compliance data of all 41 patients in percent over time. Dotted line indicates the cut-off of 75% compliance

psoriasis and  $n=1$  because of anxiety episodes during treatment). The other two patients eventually exceeded the 75% mark while maintaining therapy. Some patients dropped below the 75% mark due to progressive disease associated with clinical worsening or a temporary discontinuation of therapy due to skin rash. Other reasons to temporarily pause therapy for a few days were holidays or to have a “short mental break” from therapy to stay motivated.

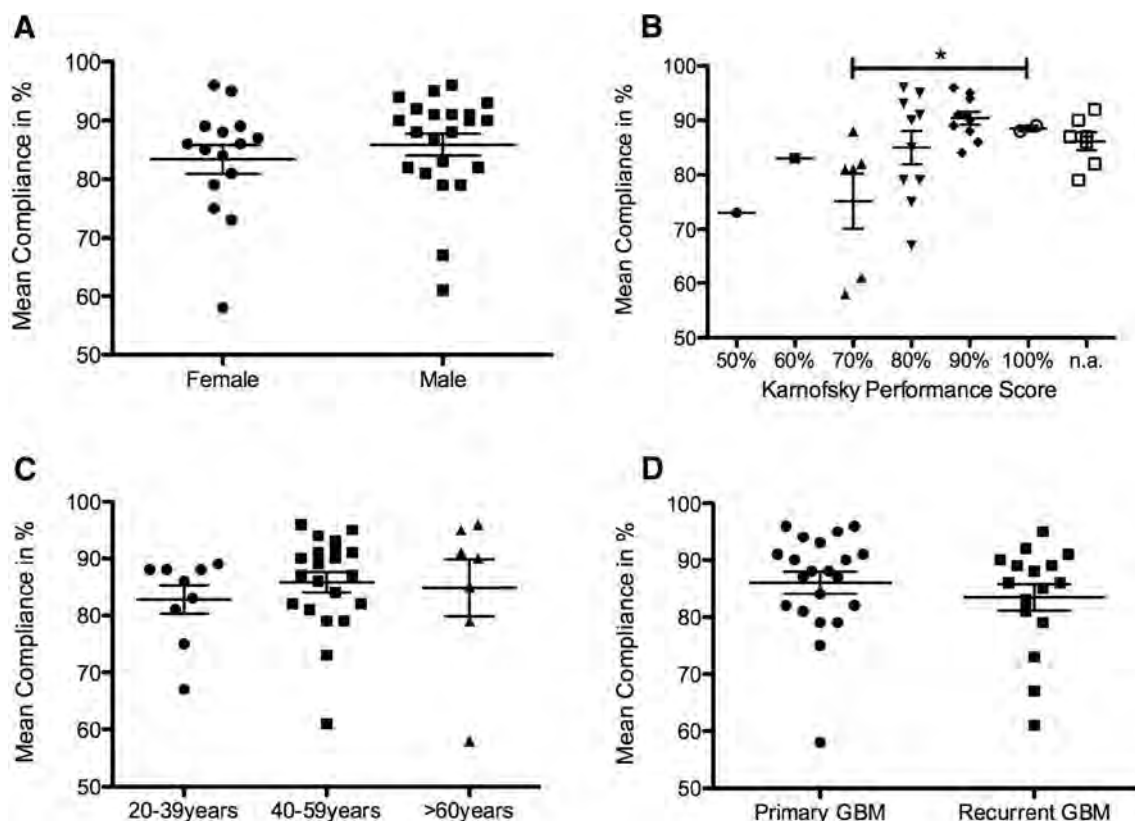

Overall, mean treatment compliance was  $84 \pm 2\%$  in female patients ( $n=15$ ) versus  $86 \pm 2\%$  in 22 male patients ( $p=0.410$ , Fig. 3a). A significant effect of KPS on compliance was seen only when comparing 70 versus 90% KPS ( $75 \pm 13\%$  vs.  $90 \pm 4\%$  [Mean  $\pm$  SD];  $p=0.017$ , Fig. 3b). However, patients in the 70% KPS group still managed to stay above 75% treatment compliance. Treatment compliance was compared among different age groups ranging from 20 to 39 years, 40–59 years and older than 59 years. No statistical difference between groups was found (Fig. 3c). Further, we assessed treatment compliance in regard to stage of disease. Mean compliance was 86% (median 87, range 40–97%) in newly diagnosed GBM versus 83% (median 86%, range 65–98%) in recurrent GBM (Fig. 3d,  $p=0.400$ ). Neither sex, age, KPS, nor stage of disease had significant

influence on treatment compliance. Our data showed that the compliance did not negatively correlate with time on treatment and compliance even stabilized once therapy was established.

## Discussion

In this study we show that TTFields are well accepted by GBM patients who are considered eligible/appropriate by the prescribing physician. Once patients have decided to accept TTFields, compliance rates are high and compare favorably to the data of the EF-14 study [11]. Our study shows that the goal being on therapy for 75% of the time can be achieved independently of age, sex, stage of disease or therapy duration.

Our patient cohort displayed a relatively low median age. This reflects the fact that younger patients tend to search more for additional treatment modalities and are more open-minded to accept relatively “new” treatment concepts to prolong survival. The lower median age explains the higher than normal rate of IDH mutations.

**Fig. 3** **a** Mean treatment compliance of male and female patients who received TTFields. **b** Mean treatment compliance in dependence of Karnofsky Performance Score,  $*p=0.017$ . **c** Mean treatment compli-

ance in dependence of age and primary versus recurrent glioblastoma (GBM) diagnosis (**d**)

According to the EF-11 trial and PriDe registry, TTFields should be applied at least 75% of the time in order to be as efficient as possible [14–16]. The comparably high compliance towards TTFields in this cohort possibly rely on the careful patient education and the staged approach of introducing this new therapy to the patient. In our view, an open, fair and honest information provided to the patient is crucial for acceptance and compliance to therapy. We openly inform patients about the logistics of the therapy, side effects, and the need for an adjusting phase of up to 4 weeks for patient and caregivers to get familiar with the everyday challenges of the therapy. Offering solutions beforehand makes the occurrence of these events more easily tolerable for the patient. In our view this certainly contributed to high therapy compliance even when encountering problems because patients knew beforehand about possible obstacles and handled them with more ease.

Due to the retrospective study design, results need to be interpreted carefully. On the other hand, the systematic user records of the device guarantee high data quality interpreting therapy compliance. Records show therapy compliance seems to depend more on the overall clinical status than on age alone. Even patients at the age > 59 years showed a remarkable average compliance far above 80% of the time and should be considered for TTFields if in good clinical condition and willing to use TTFields. KPS score is not associated with a substantial drop of compliance when above 70%. And even with a KPS of 70% the compliance is in the efficient range > 75% (Fig. 3b). On the other hand, patients who are wheel chair bound due to hemiparesis and have a formal KPS of 60% with strong request for additional treatment to chemotherapy might handle the device properly as well. Hence, we recommend not withholding TTFields in these cases and instead having an open discussion about the possibility of TTFields considering social support, patient's wish, biological age, etc.

In this study we show that compliance is equal in female and male population. Female to male ratio was 1:1.56 thus reflecting a typical GBM patient population (1:1.64) [17]. Additionally, there is no significant difference of compliance between patients with newly diagnosed and recurrent GBM suggesting that the stage of the disease does not play a big role for the acceptance and feasibility of the treatment. Since TTFields take time to be fully effective, compliance should be maintained on a high level to stay effective [18, 19]. Fortunately, compliance did not correlate negatively with time on treatment. Once patients are on therapy they mainly kept stable compliance over time, making TTFields suitable for long-term therapy. A drop in KPS almost exclusively showed progressive disease and clinical worsening that eventually led to therapy discontinuation. Treatment duration was 7.2 months for patients, which is comparable to the experience from the EF-14 study [6].

The low acceptance rate might be explained by restrained offer to elderly patients (> 70 years) and disabled patients or those having a reduced clinical status. We further assume that barriers to physicians introducing TTFields are not only concerns about patient compliance, but much more so nihilism about efficacy despite clinical trial data. Another reason to withhold therapy could be reluctance to accept mechanism of action of the therapy that differs significantly from standard chemo- or radiotherapy induced cytotoxicity.

From the patient side, there are mostly personal reasons for rejecting TTFields. Only 58/175 patients (33%) were deemed eligible for therapy by prescribing physician providing a careful selection process before offering therapy. Of these 58 patients, 37 (64%) rejected therapy due to the above stated reasons despite being offered solutions to possibly rectify encountered problems. Acceptance rate was 36% (21/57 patients) in the preselected cohort. Recently published data show that acceptance of TTFields increased up to 68% in newly diagnosed GBM patients by a more patient-centered consultation strategy [20].

We conclude that since we have demonstrated efficient compliance independent of age, sex, KPS and stage of the disease, TTFields should not be withheld from patients with advanced age or other comorbidities. Further improvement of technology resulting in decreased device size and weight will potentially also lead to improved handling and quality of life [18, 21]. Long-term use does not seem to affect compliance and allows efficient treatment even when exceeding 1 year. Thus, these criteria are not restricting possible TTFields candidates. To further improve acceptance for TTFields it is necessary to systematically assess reasons for refusing TTFields and improve these factors [22].

## Abstract

Glioblastoma is an aggressive brain malignancy with poor outcomes. Current standard of care involves surgery, radiotherapy and chemotherapy. Even with optimal treatment, 5-year survival rates are low. Many patients are unable to tolerate the considerable side effects that therapy involves and suffer from low quality of life. Anti-mitotic tumor treating fields have shown potential in treating glioblastoma with data suggesting that they prolong disease-free survival and overall survival. Novocure has marketed a device that generates these fields via externally placed electrodes. Incorporation of electric field therapy into GBM treatment has been somewhat slow, due to concerns about cost, practicality of its usage from a patient perspective, and hesitation of the medical and scientific community to embrace its unconventional mechanism. However, clinical trials have demonstrated this therapy has relatively minor side effects and high patient compliance. In this review, we explore the current state of this technology and discuss the benefits and limitations of tumor treating fields.

**Keywords** Tumor treating fields · Glioblastoma · Cancer · Minimally invasive

## Introduction

Glioblastoma (GBM), a primary brain malignancy that accounts for 17% of all primary brain tumors [1], carries a poor prognosis with a 27% 2-year survival rate [2] and a median survival of 10–11 months with standard treatment [3]. The impact of this disease has spurred considerable investigation into potential treatments, but only a few have been associated with improved survival [4–6]. Quality of life is also an important consideration as the neurologic decline associated with disease progression combined with the toxicity of experimental chemotherapies has increased the need for new treatments for GBM to strike a balance between efficacy and tolerability. In 2011 Novocure's Optune Device, a novel therapy which applies alternating electrical fields or tumor treating fields (TTFs) to damage rapidly dividing tumor cells [7], was given FDA approval for treatment of recurrent GBM, with the approval expanded in 2015 to

include newly diagnosed GBM. Despite these approvals, incorporation of TTFs into GBM treatment has been somewhat slow, due to concerns about its cost, practicality of its usage from a patient perspective, and some slowness of the medical and scientific community to embrace its unconventional mechanism. In this article we will review the theory behind TTFs for cancer treatment. We will discuss recent clinical trials involving TTFs and the likely impact this technology will have in GBM treatment.

## Current standard of care

Glioblastoma has proven exceptionally resilient to treatment. Conventional treatment can typically be lumped into one of three categories: surgery, radiotherapy and chemotherapy [8, 9]. The first major tenant of GBM therapy is surgical resection. This has been shown to increase quality of life as well as prolong survival [8–10]. It has additionally been shown that extent of resection is a predictor of overall survival, with more extensive removal correlating with improved survival [11]. However, resection is not a curative approach [11, 12]. Therefore, providers often seek to augment the benefits of resection with radiotherapy and chemotherapy. The benefits of radiation therapy and TMZ after surgery have been well elucidated in the European Organization for

Research and Treatment of Cancer (EORTC) Brain Tumor and Radiotherapy Groups and the National Cancer Institute of Canada (NCIC) prospective study. This study determined that 27.2% (95% CI 22.2–32.5) of patients treated with both radiation therapy and chemotherapy survived to at least two years, compared to 10.9% (95% CI 7.6–14.8) with radiation therapy alone [13]. Alternatively, for patients that are not able to tolerate surgery or chemotherapy, radiation therapy is able to improve quality of life and increase survival alone [14]. Therefore, variants of surgery, radiotherapy, and chemotherapy have become staples of GBM treatment, but there is significant room for improvement. This is especially true for elderly patients, who may not be able to endure the significant burden of full-course chemotherapy and/or surgical resection [15].

### Preclinical study of electrical fields in cancer suppression

In addition to the approaches described above, the use of electric fields for cancer therapy has received great enthusiasm, if not a modicum of controversy about cost and efficacy. The Optune device is the best example of this technology and uses low intensity, intermediate frequency alternating fields to suppress cancer growth [16–18]. The Optune technology represents a prime example of bench-to-bedside translational medicine.

Electric fields have played a significant role in biology for many decades. Electroporation, the application of high intensity, high frequency electrical fields to facilitate cellular DNA transfer, is an essential technique of modern genetic experiments [19]. Similarly, intermediate intensity fields have been shown to cause cellular rotation and microscopic molecular alignment [20]. These phenomena are observed because many cellular substructures are composed of charged elements and thus are subject to electrical forces when an electric field is present [19–22]. Alternatively, as is the case with electroporation, minute differences in membrane potential (transmembrane voltage) in the presence of an electric field can reorganize membrane structure to create apertures [19]. In addition to applications in the basic sciences, electric fields have numerous clinical applications. For example, high frequency electric fields cause tissue dielectric energy loss and subsequent radioablation of nearby structures [23]. On the other end of the spectrum, low frequency electric fields have the capability of depolarizing nearby tissue and have applications in nerve conduction studies and cardioversion [24]. It was believed that intermediate frequency fields, which do not exhibit tissue heating or membrane depolarizing properties, would have limited clinical applications [19, 25].

In 2004 Kirson et al. demonstrated that very low intensity ( $<2$  V/cm) intermediate frequency (100–300 kHz) fields were capable of slowing tumor replication in vitro using cell culture and in vivo using mouse models [26]. The initial in vitro work demonstrated that multiple cell lines had impaired growth in the presence of the tested electric fields and that this effect persisted for at least 72 h after treatment. Follow-up microscopic analysis of cells treated with electric fields showed impaired depolymerization/repolymerization of the mitotic spindles and resulted in atypical mitoses and cell destruction. The authors also noted the significance of electric field orientation in respect to cellular layout—a point with significant clinical implication later. The work piloted by Kirson et al. has inspired a number of in vitro follow-up studies with intriguing results. Giladi et al. demonstrated that pancreatic tumors treated with TTFs increase in overall size, indicating both disruption of the mitotic cycle and possible dysregulation of cytoskeletal elements necessary for osmotic stasis [22]. More importantly, they were also able to show that TTF treated pancreatic cancer cells were less clonogenic than untreated controls. This reflected inability to generate new clonal lineages, likely due to aneuploidic divisions that were incompatible with further mitosis. These findings were further supported by the same authors in a paper the following year that concisely demonstrated the destructive effects of TTF on spindle apparatus formation by microtubule dysregulation [27]. Lastly, a study published this year identified that the mitotic dysregulation may make treated cells more susceptible to PARP inhibitors and ionizing radiation and suggests expanding the clinical role of TTFs [28].

The optimism generated from the in vitro work has inspired application of TTF into in vivo models. The seminal work by Kirson et al. contained the first application of TTFs to a living model and probed the possible use of this technology as a therapy [26]. These investigators, like many that followed, generated electric fields by surgically implanting wires into animal models—the technology to generate these fields less invasively came later. Using these fields, Kirson et al. showed an average 47% reduction in melanoma tumor size ( $p=0.001$ ) in mouse models. The application of these fields has been extended to other animal models and has shown efficacy in other tumor types, including lung, pancreatic and brain primary malignancy [22, 26–29]. In rabbits with melanoma metastases to the lungs, median survival was increased to 70 versus 57 days in controls [30]. This same work also demonstrated that treated rabbits and mice had fewer surface lung lesions and fewer large ( $>3.0$  mm) parenchymal lesions. While these teams were able to demonstrate efficacy in numerous animal models, the use of less conventional species has made replicating these findings more challenging. Follow-up studies in rabbits have been particularly limited despite being a foundational model for

this technology. Other investigators have shown that chemotherapy efficacy is potentiated in TTF treated animals [28, 31, 32]. This finding supports *in vitro* studies that proposed a synergistic effect of DNA damaging chemotherapeutics and TTF induced mitosis disruption. Additionally, the concept was extended to study intracranial tumors using externally placed electrodes [29]. This allowed multiple fields to be placed operating in three directions (0°, 45° and 90°) and showed a 53% reduction in tumor growth of intracranial GBM in mice ( $p=0.01$ ).

## Completed clinical trials

The work with *in vivo* models allowed TTF technology to mature into a clinically acceptable, minimally invasive tool for patient trials. Promising data in animal models engendered enough enthusiasm for a prospective clinical trial to test this therapy. Unfortunately, the results of the initial Phase 3 trial did not live up to the effect produced by pre-clinical study. This trial, EF-11 ( $n=120$  treated patients), was limited in scope and only applied TTF therapy in patients with recurrent GBM [33]. Patient populations suffered from significant heterogeneity, many were on their third recurrence and had failed chemotherapy numerous times. Additionally, the control arm was assigned to receive best physician-choice chemotherapy. TTF patients had a 6.6 month median survival, compared to 6.0 months in control arm ( $p=0.27$ ) and progression free survival of 2.2 months, compared to 2.1 months in controls ( $p=0.13$ ). However, side-effects from TTF were very modest and mostly consisted of skin irritation from the transducer pads [34]. The overall impression of this trial was two-fold: (1) In terms of survival and tumor progression, TTF therapy was not significantly worse than physician-choice chemotherapy for recurrent GBM and (2) TTF had a favorable side-effect profile and better overall quality of life than physician-choice chemotherapy.

While the first clinical trial suggested that TTFs were safe, there was still a need to test their effectiveness in patients with less advanced disease. In 2009 Novocure initiated a clinical trial to determine the impact of TTFs in conjunction with chemotherapy [35]. As described above, a number of preclinical studies had suggested that TTFs could potentiate the effects of chemotherapy. This trial, EF-14, involved patients with newly diagnosed glioblastoma who were treated with TTFs and temozolomide, or a control group treated with temozolomide alone. All patients had radiotherapy and TMZ before being randomized. The distribution of gross total and sub-total resection was comparable between the two cohorts. Initial analysis of this trial showed significantly improved progression-free survival (HR 0.62, 98.7% CI 0.43–0.89,

$p=0.001$ ) and significantly improved overall survival (HR 0.74, 95% CI 0.56–0.98,  $p=0.03$ ) in intention to treat analysis. Additionally, the patients randomized to TTF did not experience any significant toxicities and the treatment was well tolerated in the trial [36–38]. A final analysis of this study was released in December of 2017 and reported a median progression free survival (PFS) of 6.3 months in TTF treated patients, compared to 4 months in the control arm [39]. While this demonstrates that TTF treated patients had improved PFS, it is notable that the control PFS of 4 months is quite a bit lower than the 6.9 months of PFS reported in TMZ/radiotherapy treated patients in other studies [40, 41]. Lastly, the median survival of the TTF treated patients was 20.9 months, compared to the 16.0 months in the control group ( $p=0.001$ ). These findings have largely been corroborated by Mrugala et al. in their chart review of the Patient Registry Dataset (PRiDe) [42]. These authors reported markedly improved survival in patients with at least 75% daily compliance with the TTF protocol (HR 0.43,  $p=0.0001$ ). A notable limitation of both the EF-14 trial and the data from the PRiDe dataset is the lack of a true placebo control. EF-14, a randomized clinical trial, could have controlled for non-TTF treatment effect by applying a non-functional device to control patients. This additional measure could blind participants and providers more effectively and better determined the benefit of this device.

## Pending clinical studies

At the time of this report, there were 11 ongoing clinical trials for TTFs in GBM (Table 1). Although there has been demonstration of efficacy thus far, the exact role that TTFs should play in patient care is still evolving. Four of the current studies are assessing the role of the anti-angiogenesis agent bevacizumab, a monoclonal antibody against vascular endothelial growth factor A, as a supplement for TTF therapy [43, 44]. Although bevacizumab currently serves a limited role in current GBM management, it may have a synergistic effect when combined with TTFs [45]. One study is aiming to assess the effects of combined tumor-derived vaccine and TTF [46]. Another study is collecting specimens from deceased patients in the hope of identifying genetic changes that are induced with TTF therapy. It should lastly be noted that Novocure is assessing the application of TTF technology to other cancers, including lung, ovarian, pancreatic and mesothelioma malignancies. The data from these trials will likely inspire further work in glioblastoma and better define the role of TTFs.

HUMC 1612: Optune NovoTTF-200A System	12	I	NCT03128047	Determine safety and tolerability of TTF in pediatric patients with high-grade glioma
NovoTTF Treatment Signatures in Glioblastoma Patients at Autopsy	20	–	NCT03194971	Identify tumor genetic signatures in patients treated with TTFs
Safety and Immunogenicity of Personalized Genomic Vaccine and Tumor Treating Fields (TTFs) to Treat Glioblastoma	20	I	NCT03223103	Test effects of personalized anti-tumor vaccine in combination with TTFs
NovoTTF Therapy in Treating Patients With Recurrent Glioblastoma Multiforme	30	II	NCT01954576	Measure effect of TTF therapy on recurrent GBM (Bevacizumab resistant and naïve)
Evaluating Therapeutic Response to Novo-TTF	30	–	NCT02441322	Determine if echo planar magnetic resonance spectroscopy (EPRS) is able to measure TTF effects on GBM
NovoTTF-200A and Temozolomide Chemoradiation for Newly Diagnosed Glioblastoma	10	I	NCT03232424	Safety and tolerability of TTF, TMZ and radiation therapy in combination. This study will involve brief application of TTF before radiosurgery and then reapplied after radiosurgery
A Phase II Study of Optune (NovoTTF) in Combination With Bevacizumab (BEV) and Temozolomide (TMZ) in Patients With Newly Diagnosed Unresectable Glioblastoma (GBM)	46	II	NCT02343549	TTFs will be applied after best standard of care radiation, temozolomide and bevacizumab
TTFs and Pulsed Bevacizumab for Recurrent Glioblastoma	25	II	NCT02663271	Continuous TTF therapy with repeat cycles of bevacizumab
Optune® Plus Bevacizumab in Bevacizumab-Refractory Recurrent Glioblastoma	85	II	NCT02743078	Will determine effect of TTFs and bevacizumab in tumors that failed to respond to bevacizumab alone
Enhancing Optune Therapy With Targeted Craniectomy	15	I	NCT02893137	Craniectomy (burr holes) will be placed for patients experiencing first recurrence to measure effects of TTF electrode placement
Optune(NOVOTTF-100A) + Bevacizumab + Hypofractionated Stereotactic Irradiation Bevacizumab-Naïve Recurrent Glioblastoma	27	–	NCT01925573	Determine safety and activity of TTFs, bevacizumab and hypofractionated radiosurgery in combination

## Limitations to date

As a novel technology, TTFs present a unique set of limitations to their use. In order to work effectively, the transducer pads must be applied directly to the skin [47]. Patients must shave their heads to allow the treatment pads to contact their scalp. The pads are applied with an adhesive and are usually changed every 3–4 days. While the pads are in place, patients must keep them dry, which can make bathing and recreational activities that involve water difficult. Once applied the device should be active 18 h a day to meet current recommendations. To make this possible, patients carry portable battery packs that supply energy to the transducers. Patients are free to travel, but must be able to change the batteries of their device every few hours. Each device comes with its own charging station and set of batteries. Therefore, patients must be willing to accept the limitations of the transducer pads, be willing to change batteries for the device every few hours, and keep their head shaved. Despite these requirements, compliance rates in the initial two studies exceeded 75% [33, 35]. The most significant side effects to therapy were skin irritation from the transducer adhesive or abrasion from the array pads. Although not trivial, these lesions typically responded to topical steroids and ultimately only 1–2% of patients had to discontinue therapy from these reactions. The risk of these lesions can be reduced by using gauze to protect areas that have a higher likelihood of irritation (incision scars, implanted devices, etc.) and training caregivers to care for the device and scalp [15, 48]. The larger limitation appears to come from patients unwilling to start this therapy due to perceived inconvenience of wearing the device. Although the initial clinical trials have reported good patient compliance, this may be biased by the relatively high enthusiasm of patients willing to participate in clinical trials.

Cost has been a concern about TTFs. While many patients have been able to access this technology through clinical trials, the Optune device, like many new therapies, comes at a considerable expense. It is estimated that each additional month of life attributable to Optune costs \$21,000 [49]. Even if the efficacy of TTF technology is validated, it may be prohibitively expensive and fail to reach widespread use. Despite enthusiasm from providers and patients alike, healthcare is a limited resource and can be sapped from the costs of cancer therapy [49, 50].

## Further areas of interest

As is mentioned in the review of the preclinical literature, TTFs may alter the genetic signature of treated tumors and make them susceptible to particular chemotherapeutic

agents [7, 16–18, 51, 52]. This could potentially make glioblastoma more susceptible to mitosis inhibitors or, as discussed above, expand the application of bevacizumab in therapy. Similarly, there is preclinical data that suggests TTFs can increase the anti-tumoral effects of ionizing radiation [53, 54]. Currently TTFs are applied after patients have undergone radiation therapy, but it is possible that a brief course of TTFs should precede radiation therapy for optimum effect. Lastly, there is some early work demonstrating that TTFs may activate local immune responses and could therefore have interplay with immunotherapy in the future [55].

## Conclusion

Since their discovery in 2004, tumor treating fields have quickly advanced from the bench to the bedside. Data from randomized clinical trials has demonstrated that TTFs increase patient survival and can be readily combined with other therapies. Although this technology has been met with skepticism, rigorous clinical trials have proven that they are effective in improving survival. In predicting the future of TTFs, the efficacy of this technology against a disease with a markedly dim prognosis and its low toxicity must be weighed against considerations such as cost and patient convenience. However, the drawbacks are tempered by the fact that other glioblastoma therapies have considerable costs and burdens as well. These factors suggest that TTFs are poised to develop a meaningful market share in the treatment of newly diagnosed and recurrent GBM during the upcoming years. This is particularly true in older patients, who may be less bothered by the inconvenience, may not tolerate the side effects of more aggressive treatments, and carry an elevated disease burden. Therefore, this technology strikes a balance between efficacy and toxicity that is desirable for many patients and will likely have a growing role in glioblastoma management.

**Funding** Jonathan Rick and Ankush Chandra are supported by the Howard Hughes Medical Institute.

## Compliance with ethical standards

**Conflict of interest** The authors declare no conflict of interest.

**Research involving human and animals participants** No experiments were performed on animal or human subjects by the authors.

Tumor Treating Field (TTFields) therapy has demonstrated efficacy in a Phase 3 study of newly diagnosed glioblastoma (GB) following radiation (RT) and temozolomide (TMZ). We report the appearance of an isolated satellite anterior temporal lobe lesion, 2 months post primary RT/TMZ directed at the primary GB (MGMT methylated) parietal lobe lesion and one adjuvant cycle of TMZ and TTFields. The mean RT dose delivered to the temporal lobe lesion was negligible, i.e.,  $4.53 \pm 0.95$  Gy. Mapping of the generated TTFields demonstrated that both lesions were encompassed by a field intensity in a therapeutic range. The temporal lobe lesion remained under the control of TTFields up to 12 months, at which point progression on a T1 contrast MRI resulted in surgery and a definitive diagnosis of GB without MGMT methylation. The primary parietal lobe at this time was in remission. Molecular sequencing on the GB tissue from multiple time points demonstrates clonal evolution of the cancer over time and in response to treatment.

## INTRODUCTION

Tumor Treating Field (TTFields) therapy has demonstrated efficacy in a Phase 3 study of newly diagnosed glioblastoma (GB) following radiation (RT) and temozolomide (TMZ) (1), as well as in the recurrent setting (2). Interestingly, there have been no reports of TTFields therapy in GB patients who have not received prior RT. In addition, the potential mechanisms by which resistance to TTFields therapy develops has been understudied.

In the report to follow, an analysis of a satellite lesion that developed after standard RT and TMZ therapy in a newly diagnosed GB patient is presented. Therapy with TTFields had been initiated 1 month prior to the appearance of the satellite lesion. The patient was followed longitudinally with MRIs every 2 months; additional analysis of the radiation dose exposure, as well as the TTFields intensity, was performed. The differential diagnosis at the time included an MRI artifact or lesion induced by TTFields, vs. progressive disease. After 12 months, the aforementioned lesion

was resected. Molecular alterations from baseline, post-progression on TTFields and following a further recurrence were assayed. The results below summarize these collective findings.

## CLINICAL DETAILS AND DATA ANALYSIS

In March 2016, a 51-year old male presented with left-sided numbness and weakness. A MRI demonstrated a  $35 \times 25 \times 29$  mm partially cystic or necrotic, enhancing mass with internal hemorrhage in the right parietal lobe. Subtotal resection was accomplished in March 2016 confirming a grade 4 astrocytoma with IDH1/2 wild type, MGMT methylated, and negative 1p19q co-deletion.

Standard radio-chemotherapy was completed in June 2016 (3), including daily TMZ with a total of 60 Gy radiation give in 30 fractions; adjuvant TMZ began in July 2016. TTFields therapy (1) was initiated in July 2016 and continued until August 2017. A post-radiation MRI was done in August 2016, showing increased thickness of the residual enhancing region in the right parietal lobe in addition to a new lesion in the right middle temporal gyrus (Figure 1).

Changes of residual tumor in the right parietal lobe was presumed to be progression vs. pseudo-progression, and the patient continued with six cycles of adjuvant TMZ, which was completed in December 2016. The changes in the parietal lobe lesion resolved over time, confirming pseudo-progression. In spite of the appearance of the temporal lobe lesion, it was decided to continue therapy with both TMZ and TTFields (with frequent monitoring), as the possibility of an artifact of TTFields therapy and/or an unusual form pseudo-progression was raised.

On a series of follow-up MRIs from August 2016 to August 2017, the initial parietal lobe lesion regressed with adjuvant TMZ and appeared stable on both T1+contrast and T2/FLAIR MRIs. The new enhancing lesion in the temporal lobe (during adjuvant TTFields/TMZ therapy) decreased from 9 to 7.7 mm in diameter with decreasing enhancement from August 2016 to November 2016 (Figure 1), and stayed stable on bi-monthly follow up MRIs until August 2017. At this time the temporal lobe lesion was at 17.9 mm in diameter (on T1+contrast); the parietal lobe lesion was essentially resolved, confirming pseudo-progression of this tumor (Figure 1). T2/FLAIR images showed abnormality with an area of restricted diffusion and peripheral rim enhancement in the region of the right temporal lobe lesion. A gross total resection of the temporal lesion was achieved in August 2017, confirming a grade 4 astrocytoma, with wild type IDH1/2, unmethylated MGMT, and negative 1p19q co-deletion (Figure 2). The mean prior radiation dose for this temporal lesion was determined to be  $4.53 \text{ Gy} \pm 0.95 \text{ Gy}$  (5.7 Gy max; 3.5 Gy min; volume 0.1 mL). An isodose cloud is depicted (Figure 3). The lesion was 2.5 cm away from the edge of the planning target volume treated to full dose (46 Gy; center lesion dose 60 Gy).

The patient was then treated (September 2017–November 2017) with radiation (60 Gy in 30 fractions), targeting the temporal lobe resection cavity. An MRI in January 2018 demonstrated a possible new nodule ( $0.7 \times 0.7$  cm) on the edge

of the resection cavity. A subsequent MRI in February 2018 confirmed progression with an increase in the aforementioned nodule to  $1.4 \times 1.8$  cm. In March 2018, the patient underwent reoperation with a gross total resection as part of the TOCA 5 Tocagen Inc. clinical trial and was randomized to the control arm post-operatively. He started bevacizumab therapy in April 2018 which maintained his surgically obtained complete remission until relapse in August 2018.

Molecular analyses demonstrate that at resection of the primary parietal lobe lesion this cancer possessed mutations in *BRAF* (V600E), *PTEN* (319fs), and the *TERT* promoter (C228T). Following progression on TTFields, the separate anterior temporal lesion was resected. This lesion possessed these identical *BRAF*, *PTEN*, and *TERT* alterations, and was also found to possess a deep deletion of *CDK2NA* and an activating mutation in *mTOR* (V2006I). The lesion in the anterior temporal lobe that recurred following radiation was also sequenced following resection. This lesion was hypocellular, and similar to the prior resection exhibited mitosis, nuclear atypia and no necrosis; the same *BRAF*, *mTOR*, and *TERT* abnormalities were still able to be observed. No new alterations were detectable in this sample.

Additionally, a retrospective analysis demonstrated the TTFields intensity was in a therapeutic range for both the parietal lobe and temporal lobe lesion, i.e., 1 V/cm (Figure 4).

## METHODS

### Bio-Marker Testing

MGMT testing performed by LabCorp, NC; IDH testing done by PCR, UW Health Clinical labs, WI, 1p19q testing by FISH, Wisconsin State Laboratory of Hygiene.

### Determination of Radiation Dose

Using image registration software (Mim Vistag Cleveland, OH) that imports the radiation dose, the axial contrast-enhanced 3D T1-weighted images (T1 3D-SPGR Bravo, GE Healthcare, Waukesha, WI) were fused into a coordinate system of the treatment planning CT. A region of interest was drawn around the anterior temporal lobe lesion, and dosimetric analysis revealed the prior RT dose to the lesion.

### Mapping of TTFields Intensity

In order to estimate field intensity distributions within the lesions, numerical simulations were performed using finite differences Time Domain (FDTD) calculations and a realistic head model as described in Wenger et al. (4). Briefly, a realistic head computational model of a healthy male was created and scaled to match the dimensions the patient's head. Transducer arrays for the delivery of TTFields were positioned on the head model to mimic the personalized transducer array layout that was placed on the patient. In order to establish whether or not TTFields were delivered at therapeutic levels to the tumors, ellipsoidal regions approximately encompassing the lesions were manually marked on the field intensity maps. The field was considered to deliver TTFields at therapeutic levels to the lesion if the median field intensity within the respective ellipsoid exceeded 1 V/cm (5).

**FIGURE 1 | (A)** T1+contrast MRI images: Upper panels are right temporal lobe; lower panels are corresponding right parietal images. *Baseline* (Aug. 2016) demonstrates the first appearance a temporal lobe lesion ~2 months post radiation/temozolomide; the lower panel demonstrates the primary GB. Middle section ~11 months later (June 2017) demonstrates slightly less enhancement of the temporal lobe lesion, and a dramatic reduction in enhancement and size of the parietal lobe lesion with decreased edema and treatment related cerebral atrophy. At ~12 months (Aug. 2017) the temporal lobe lesion has increased to 18 × 13 mm; the parietal lobe remains stable and in remission. **(B)** StrataNGS cancer hotspot sequencing was performed on the resection of the primary parietal lobe lesion, which possessed mutations in *BRAF* (V600E), *PTEN* (319fs), and the *TERT* promoter (C228T). Following progression on TTFields, the separate anterior temporal lesion was resected and demonstrated *BRAF*, *PTEN*, and *TERT* alterations, and the acquisition of a deep deletion of *CDK2NA* and an activating mutation in *mTOR* (V2006I). No other pathologic alterations were identified in the remaining 47 genes of the 88 genes assessed.

**FIGURE 2 | (A)** H&E stained section of right parietal tumor at original magnification of 40x, reveals a densely cellular astrocytic neoplasm with nuclear atypia, mitosis, and vascular endothelial proliferation. Palisaded necrosis was also present but not shown in this field. **(B)** H&E stained section of right temporal mass at original magnification of 40x, also reveals a densely cellular astrocytic neoplasm with slightly more gemistocytic features, nuclear atypia, mitosis, and vascular endothelial proliferation that was similar to the previously resected tumor. This material lacked necrosis.

## Strata Oncology Hot Spot Sequencing

Patient samples were sequenced through STRATA Oncology CLIA-certified laboratory using the StrataNGS platform. This panel covers 88 genes and examines predefined variants

including single and multinucleotide alterations, small insertions/deletions, fusions, exon skipping mutations, copy number variation, and microsatellite instability ([www.strataoncology.com](http://www.strataoncology.com)).

## DISCUSSION

In this report, we present the first instance of a grade 4 astrocytoma controlled by systemic TMZ and TTFields, with negligible radiation exposure. The patient's initial parietal lobe lesion was MGMT methylated, not IDH mutated, and not 1p19q deleted; the resected temporal lobe lesion was similar histologically, but was not MGMT methylated. Based on the

MRIs between June 28th to August 14th, 2016 (**Figure 1**), the volume doubling time was calculated (6) as 14 days for the temporal tumor.

As the temporal lobe tumor appeared after initial concurrent radiation and TMZ treatment, this tumor may have been TMZ resistant, which is consistent with the absence of methylation on MGMT promoter. Alternatively, a resistant TMZ clone may have evolved over time. The initial radiation field was reconstructed, showing that the temporal lobe was exposed to minimal radiation at the time,  $4.53 \pm 0.95$  Gy. This region, however, was within the TTFields effective region, suggesting that the suppression of tumor growth from August 2016 to 2017 was under the control of adjuvant TMZ and/or TTFields.

The original plan for the placement of Optune™ arrays using the NovoTAL™ methodology (7) targeted the right parietal lesion. It was not intuitively obvious that the field distribution in the temporal lobe region would be sufficiently high to have a therapeutic effect. Hence, numerical simulations (**Figure 4**) were performed; the simulations demonstrate that the field intensity delivered to both lesions was at therapeutic levels ( $>1$  V/cm). Taken collectively, these data support the efficacy of TTFields in a newly diagnosed GB regarding a lesion that received a negligible dose of ionizing radiation. The contribution of adjuvant TMZ in controlling this lesion is indeterminate as discussed above.

Based on the molecular sequencing we can see that the cells within the anterior temporal lobe lesion developed from cells in the original primary parietal lobe lesions as the exact alterations were identified in both instances. The additional alterations identified presumably arose through clonal selection. While many factors could have potentially played into this selection process, we propose that it is quite plausible that the activating mutation in mTOR and/or the deep loss of CDKN2A could be inducing the resistance to TTFields therapy.

Over the last few years, new mechanistic insights have been gained into the anti-cancer effects of TTFields. These potential mechanisms of action include disruption of key

**FIGURE 3 |** Demonstration of isodose cloud for temporal lobe lesion (see arrow). Purple denotes 5Gy isodose; green denotes 8.57 Gy isodose.

**FIGURE 4 |** Demonstration of the field intensity distribution in axial slices through the centers of the (A) primary right parietal lobe lesion and (B) the right temporal lobe secondary lesion. The median field intensity in the region of the primary lesion was 1.7 V/cm (mean of 1.66 V/cm). In the region of the secondary lesion the median intensity was 1.48 V/cm (mean of 1.56 V/cm). This suggests that TTFields intensities around both lesions exceeded the therapeutic threshold of 1 V/cm.

cellular functions, such as mitosis, DNA repair, mitochondrial function, and the folded protein response, leading to the induction of cellular stress, autophagy and apoptosis (5, 8–10). TTFields has also been implicated in enhancing the immune response through the induction of immunogenic cell death and modulation of antigen presentation (11). Loss of CDKN2A could lead to cell cycle dysregulation and mTOR activation could lead to inhibition of autophagy, apoptosis, and enhance cell proliferation overcoming some of the potential mediators of response to TTFields (12, 13). In addition, activation of the PI3K/AKT/mTOR signaling pathway has been associated with immune suppressive properties, including the up-regulation of the PD-L1 immune checkpoint.

In summary, this report provides evidence that TTFields may offer prolonged therapeutic benefit for some patients with recurrent GB. The molecular analysis of this patient's cancer over time provides potential insight to mechanisms by which resistance to TTFields might occur. This work also raises several interesting questions about how clonal evolution and spread through the central nervous system occurs, whether targeting therapies, such as mTOR or BRAF inhibitors, could be used in settings like this, and whether more routine molecular profiling should be obtained for patients with GB. Clearly, as we learn more about the biology of individual patients with GB this will lend itself to more precision-based treatment strategies for patients.

# AMPK-dependent autophagy upregulation serves as a survival mechanism in response to Tumor Treating Fields (TTFields)

Anna Shteingauz<sup>1</sup>, Yaara Porat<sup>1</sup>, Tali Voloshin<sup>1</sup>, Rosa S. Schneiderman<sup>1</sup>, Mijal Munster<sup>1</sup>, Einav Zeevi<sup>1</sup>, Noa Kaynan<sup>1</sup>, Karnit Gotlib<sup>1</sup>, Moshe Giladi<sup>1</sup>, Eilon D. ## Abstract

Tumor Treating Fields (TTFields), an approved treatment modality for glioblastoma, are delivered via non-invasive application of low-intensity, intermediate-frequency, alternating electric fields. TTFields application leads to abnormal mitosis, aneuploidy, and increased cell granularity, which are often associated with enhancement of autophagy. In this work, we evaluated whether TTFields effected the regulation of autophagy in glioma cells. We found that autophagy is upregulated in glioma cells treated with TTFields as demonstrated by immunoblot analysis of the lipidated microtubule-associated protein light chain 3 (LC3-II). Fluorescence and transmission electron microscopy demonstrated the presence of LC3 puncta and typical autophagosome-like structures in TTFields-treated cells. Utilizing time-lapse microscopy, we found that the significant increase in the formation of LC3 puncta was specific to cells that divided during TTFields application. Evaluation of selected cell stress parameters revealed an increase in the expression of the endoplasmic reticulum (ER) stress marker GRP78 and decreased intracellular ATP levels, both of which are indicative of increased proteotoxic stress. Pathway analysis demonstrated that TTFields-induced upregulation of autophagy is dependent on AMP-activated protein kinase (AMPK) activation. Depletion of AMPK or autophagy-related protein 7 (ATG7) inhibited the upregulation of autophagy in response to TTFields, as well as sensitized cells to the treatment, suggesting that cancer cells utilize autophagy as a resistance mechanism to TTFields. Combining TTFields with the autophagy inhibitor chloroquine (CQ) resulted in a significant dose-dependent reduction in cell growth compared with either TTFields or CQ alone. These results suggest that dividing cells upregulate autophagy in response to aneuploidy and ER stress induced by TTFields, and that AMPK serves as a key regulator of this process.

## Introduction

Tumor Treating Fields (TTFields) are an established anti-mitotic treatment modality delivered via non-invasive application of low-intensity (1–3 V/cm), intermediate-frequency (100–300 kHz), alternating electric fields to the tumor region<sup>1–3</sup>. In a randomized phase 3 study (NCT00916409) TTFields in combination with

maintenance temozolomide significantly prolonged progression-free and overall survival of newly diagnosed glioblastoma patients when compared with patients receiving maintenance temozolomide alone<sup>4</sup>. Previous studies have demonstrated the effectiveness of TTFields application in various cancer cell lines, as well as in in-vivo models and in the clinical setting<sup>2,3,5–7</sup>. TTFields intrinsically affect molecules that possess high electric dipole moment and promote a number of anti-mitotic effects including the disruption of the spindle structure through microtubules depolymerization and perturbation of cytokinesis through mitotic Septin complex

mislocalization, both of which may ultimately lead to mitotic catastrophe<sup>3,8,9</sup>.

More recent studies have also revealed the inhibitory effects of TTFields on cell migration and invasion via downregulation of phosphoinositide 3-kinase (PI3K)/AKT/nuclear factor- $\kappa$ B signaling<sup>10</sup> and the capability of TTFields to sensitize cancer cells to radiation by impeding the DNA damage response, possibly through downregulation of the BRCA1 signaling pathway<sup>11–13</sup>.

Several studies have shown that cells treated with TTFields demonstrate an increase in cell volume and granularity<sup>9,14</sup>. Increased cellular granularity is typically associated with senescence and autophagy<sup>15,16</sup>. As senescence was not detected in cells treated with TTFields, we hypothesized that the origin of the observed granularity may be due to the accumulation of autophagosome vesicles<sup>8</sup>. A recent study supports this hypothesis by providing evidence that TTFields induce autophagy in glioma cell lines<sup>17</sup>. Observations that autophagy was stimulated under stress conditions and was shown to be involved in cell survival and proliferation have prompted interest in the relevance of autophagy in human disease, including cancer, and its role in treatment resistance<sup>18,19</sup>. The role of autophagy in cancer is complex<sup>20,21</sup>. Autophagy can have a tumor suppressive function at early stages of cancer development and promote tumor cell survival in

established tumors<sup>22</sup>. Autophagy also facilitates the resistance of tumor cells to anticancer agents<sup>23</sup> and to radiation<sup>24</sup>.

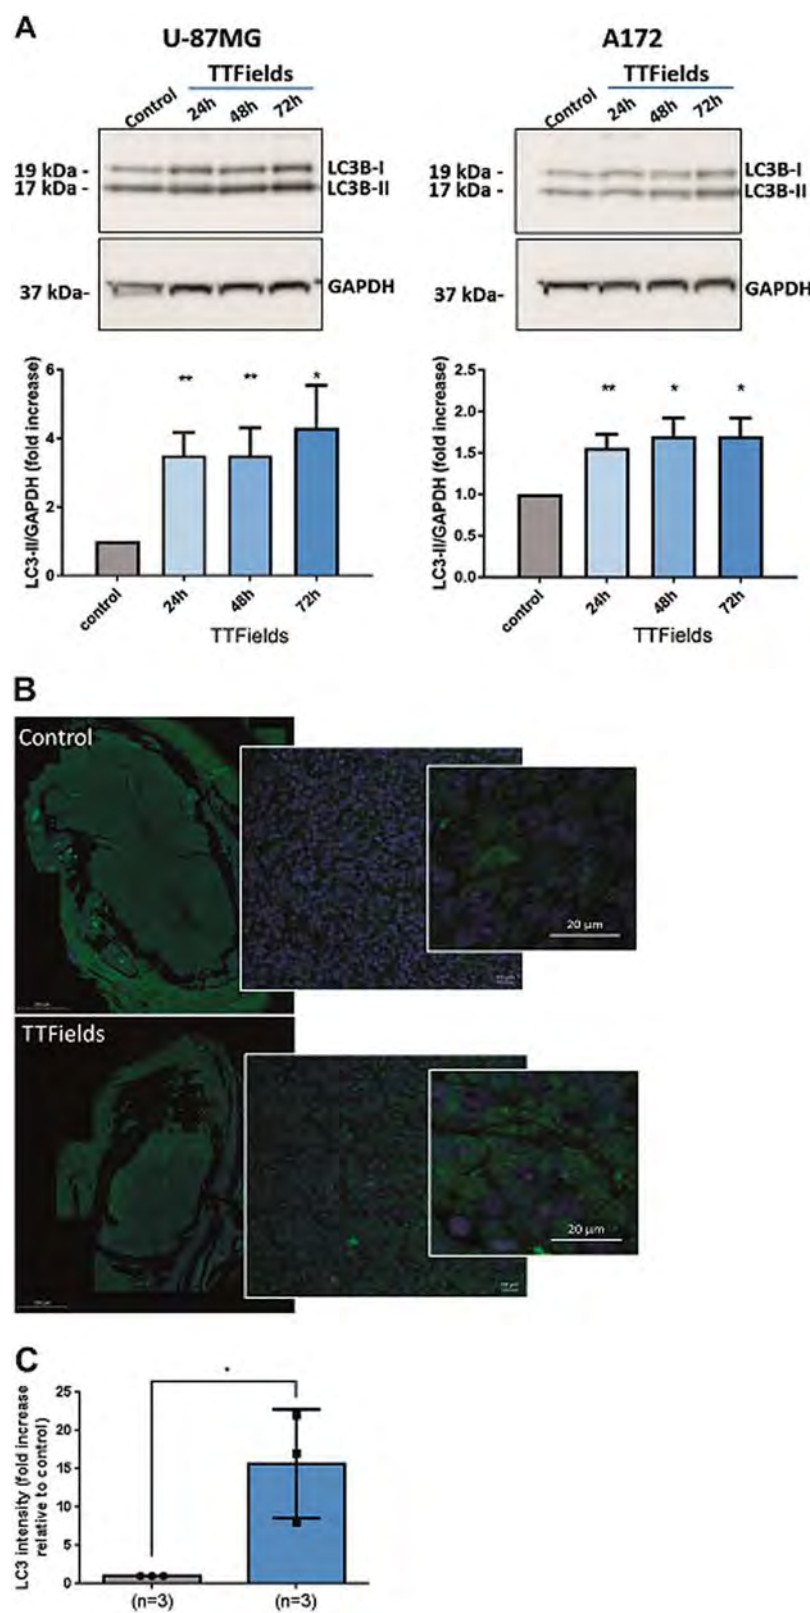

The objective of the current work was to understand the effects of TTFields on cancer cells in terms of autophagy. Specifically, we show that the abnormal mitosis induced by TTFields upregulate proteotoxic stress response leading to AMP-activated protein kinase (AMPK) activation and increased autophagic flux in treated cells. Our findings support that the enhanced autophagy serves as a resistant mechanism to TTFields, which could be circumvented by targeting autophagy.

## Results

### Effects of TTFields on cellular granularity

To establish whether changes in cell granularity are a common outcome of TTFields application, we used flow cytometry analysis of side-scatter parameters (i.e., granularity), in various cancer cell lines, including the following: mesothelioma (MSTO-211H), glioma (U-87 MG, A172, LN229), lung (LLC-1, KLN-205), and pancreatic (AsPC-1) cancer<sup>25</sup>. In all cell lines tested, TTFields application resulted in changes in cellular granularity (Fig. 1a, b)<sup>25</sup>. This can potentially be attributed to lysosomes accumulation, which was confirmed by fluorescent microscopy of LysoTracker-stained cells, which

**Fig. 2** (See legend on next page.)

(see figure on previous page)

**Fig. 2 TTFields induce autophagy in glioma cell lines.** **a** U-87 MG and A172 cells were either left untreated or treated with TTFields at the last 24 h, 48 h, or 72 h of culturing. All cultures were plated on the same time, incubated overnight to allow cell attachment, and collected 72 h afterwards. Cells were collected, lysed, and samples were analyzed using immunoblotting for LC3 and GAPDH. Upper panel: representative blots. Lower panel: densitometric quantification of immunoblot signal, showing an average of at least three independent experiments ( $0.01 < *P < 0.05$ ,  $**P < 0.01$ , Student's *t*-test). **b** Paraffin-embedded sections from sham- or TTFields-treated rats were stained with anti-LC3 Ab (green) and DAPI (blue). Representative images are presented. **c** Quantification of LC3 intensity, presented as fold increase from corresponding control ( $*P < 0.05$ , Student's *t*-test)

demonstrated larger acidic lysosomal pool in TTFields-treated cells (Fig. 1c).

### TTFields increase autophagosome formation and autophagic flux

To explore whether the appearance of the cellular lysosomes following TTFields application is attributed to autophagy, we used immunoblot assay to quantify light chain 3 (LC3) in U-87 MG and A172 glioma cell lines. LC3 is a cytoplasmic protein that on induction of autophagy is converted to LC3-II through lipidation, allowing its association to the autophagic vesicle membrane<sup>26</sup>. Immunoblot assay revealed that LC3-II signal increased after TTFields application, and that this increase in autophagosome formation was dependent on treatment duration (Fig. 2a). To test whether TTFields also increased autophagosomes formation *in vivo*, we treated Fisher rats inoculated intracranially with F98 glioma cells (as was previously reported by Kirson et al.<sup>2</sup>) with either TTFields or sham control, and stained the tumor sections for LC3. Application of TTFields was associated with noticeable increase in autophagy (Fig. 2b, c).

The accumulation of autophagosomes, as measured by LC3-II levels, may indicate sheer upregulation of autophagy or it may reflect reduced autophagosome turnover due to defects in autophagosome transport and autophagosome–lysosome fusion. Electron microscopy (EM) observation of ultra-structures revealed membrane-bound vesicles containing cytosolic materials or organelles, and the presence of degradative autophagic vacuoles containing partially degraded material, which was more abundant following TTFields application, indicating the existence of autophagic structures and an effective fusion process (Fig. 3a; blue and green arrows).

To further validate these observations, Chloroquine (CQ; a known inhibitor of lysosomal degradation) was added 3–4 h before treatment end. The addition of CQ, which prevents LC3-II degradation and release back to the cytoplasm, resulted in a significant increase in the LC3-II levels in cells treated with TTFields relative to control cells, as shown by immunoblotting (Fig. 3b, Supplementary Figure 1), immunofluorescent staining for quantification of LC3 puncta (Fig. 3c), as well as autophagic vacuoles accumulation using EM (supplementary figure 2).

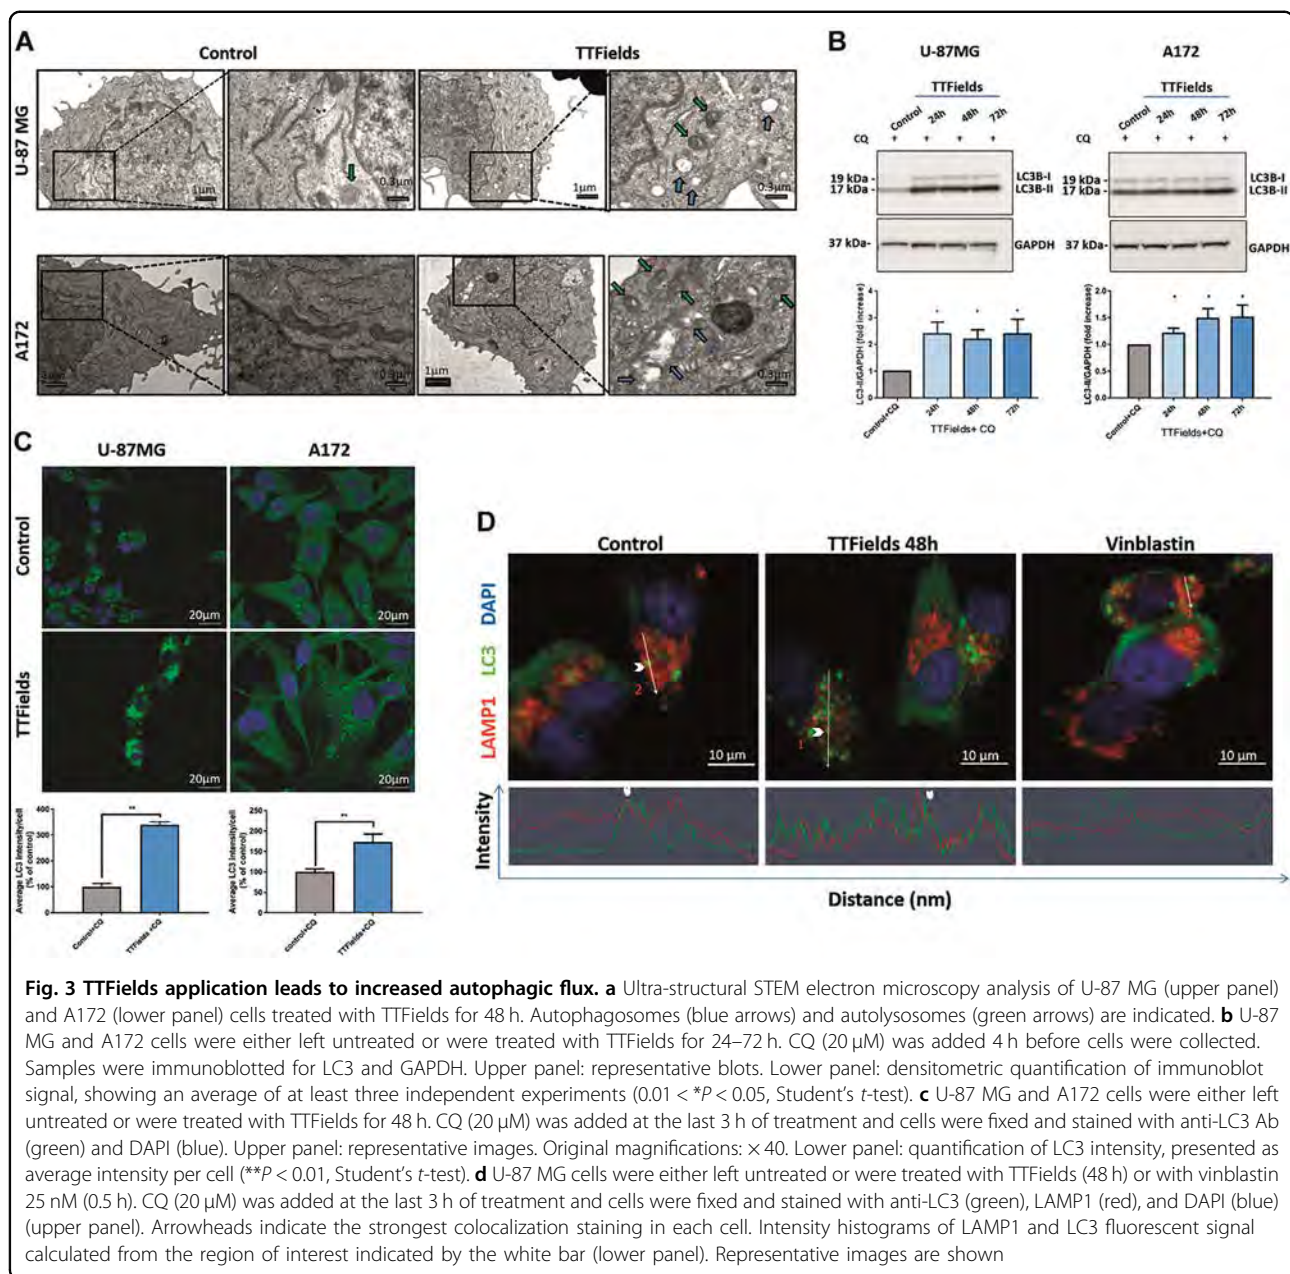

Direct evidence for normal autophagosome-to-lysosome fusion under TTFields application was obtained using immunofluorescent staining of LC3 foci with the lysosomal marker LAMP1. Unlike vinblastine, a known inhibitor of autophagosome trafficking, which led to dispersed localization of the two markers, TTFields application did not perturb LC3 and LAMP1 colocalization (Fig. 3d).

Taken together, these results demonstrate that TTFields application lead to an increase in the autophagic flux in glioma cell lines with no substantial influence on the fusion degradation steps.

### Stress response in daughter cells produced under TTFields application upregulate autophagy

Abnormal mitosis following TTFields application results in different cell fates including the formation of aneuploid daughter cells<sup>7,8</sup>. Aneuploidy is associated with the activation of regulators of autophagic and lysosomal gene expression<sup>27,28</sup>. To explore whether autophagy was more prominent in cells that divided during TTFields application, we analyzed autophagosome dynamics within single cells using U-87 MG cell line stably expressing LC3 protein fused with green fluorescent protein (GFP). We utilized time-lapse microscopy to monitor the mitotic index, duration of mitosis, and autophagosomes formation in cells during TTFields application. We found that the mitotic index in TTFields-treated cells was somewhat lower than in control group (60% and 73% of cell population, respectively), and that the duration of mitosis was longer in treated cells than in control cells (1.5 h vs. 1 h, respectively,  $p < 0.05$ ) (Supplementary Figure 3). These results are in accordance with previously published data, which demonstrated increased rates of mitotic catastrophe during TTFields application<sup>8,9</sup>. A robust increase in LC3-GFP puncta fluorescence was revealed in 51% of TTFields-treated cells relative to 17% in untreated cells (Fig. 4a, b). Through the analysis of multiple cells, we were able to identify mitotic events within a population and track autophagosome dynamics in the resulting daughter cells (Fig. 4c). Upregulation in LC3-GFP signal was detected in cells that exhibited visible signs of abnormal mitosis such as polyploid nucleus following slippage events (Fig. 4c, white arrow). An increased LC3-

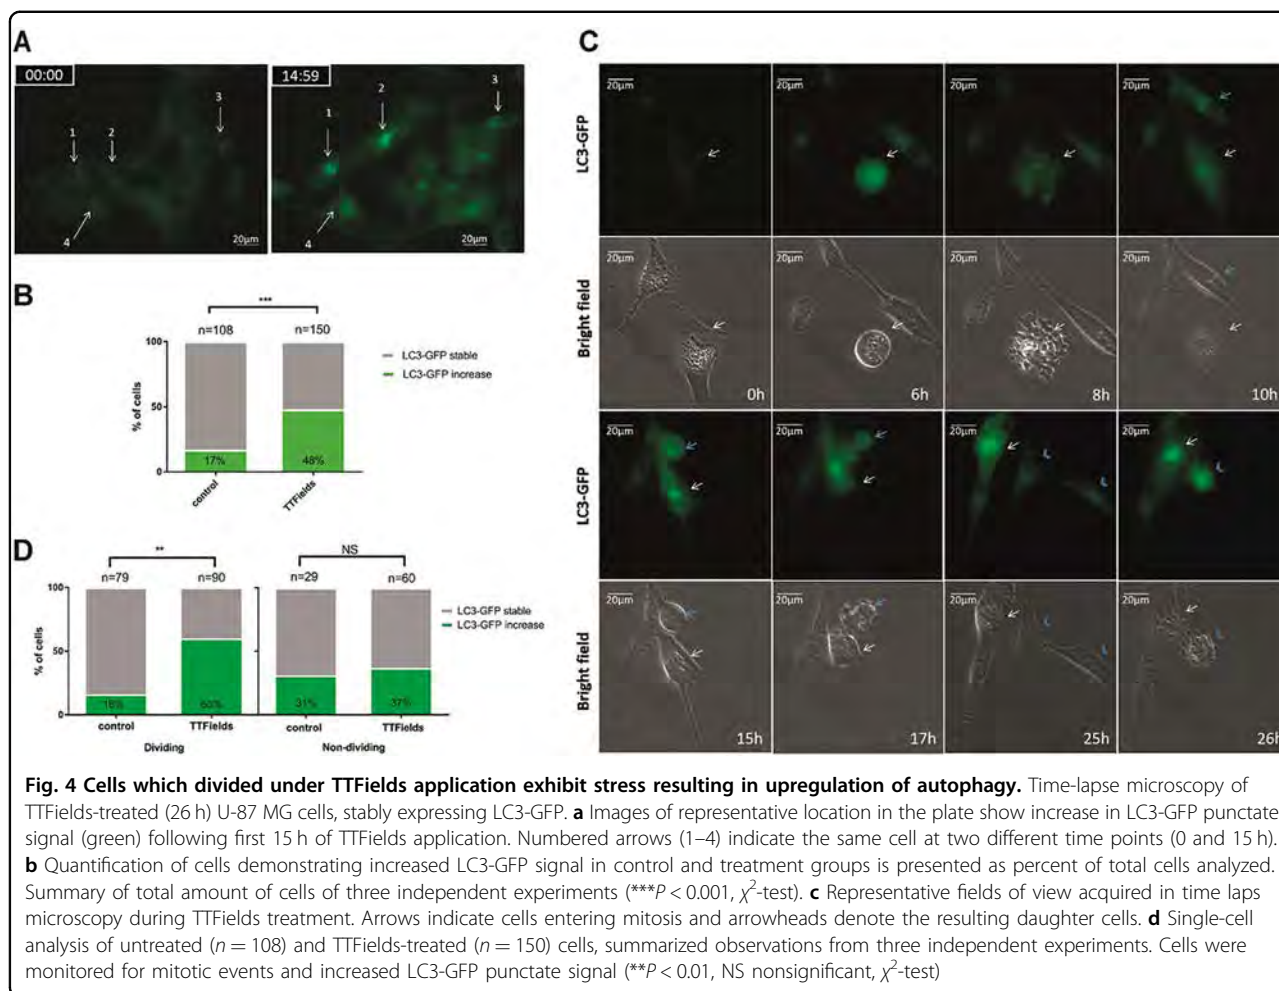

GFP signal was also detected in cells that had completed cytokinesis, but where the resulting daughter cells showed abnormal morphology (Fig. 4c, blue arrowhead). Most of the cells that divided during TTFields application showed increased LC3-GFP puncta (60%) relative to 16% of the dividing cells in the untreated culture (Fig. 4d, left). Percentage of cells that did not undergo mitosis, but showed increased LC3-GFP signal, was similar in control and TTFields group (Fig. 4d right). We conclude that the induction of autophagy following TTFields treatment is a consequence of aberrant mitosis.

#### TTFields-induced autophagy is mediated by AMPK activation

Aneuploidy-induced proteomic changes may generate proteotoxic stress, which is characterized by the engagement of protein degradation and folding pathways accompanied by additional energy requirements as reflected by low intracellular ATP levels<sup>29,30</sup>. We detected increased levels of GRP78 protein, a common marker of the endoplasmic reticulum unfolded protein response, in both A172 and U-87 MG cells treated with TTFields (Fig. 5a). In addition, intracellular ATP levels were found

to be reduced by 18% ( $p < 0.05$ ) in treated cells ( $\sim 1.2$  nmol for  $0.2 \times 10^6$  cells) relative to untreated ( $\sim 1.5$  nmol for  $0.2 \times 10^6$  cells) (Fig. 5b).

AMPK, a cardinal cellular energy sensor, is activated by various metabolic stresses and acts as a master positive regulator of autophagy by directly activating of the mammalian autophagy initiating kinase, ULK1<sup>31,32</sup>. Using immunoblot assay, we observed significantly elevated levels of phosphorylated AMPK in U-87 MG and A172 glioma cell lines treated with TTFields at the indicated time points (Fig. 5c, Supplementary Figure 4A). A sequential ULK1 activation indicated by Ser 317 phosphorylation (AMPK-specific site) was also noted (Fig. 5c, Supplementary Figure 4B).

Silencing of AMPK in U-87 MG cells, using small interfering RNAs (siRNAs; siAMPK) resulted in 80% reduction in AMPK protein levels and abrogated the increase in LC3-II levels in response to 48 h TTFields application (Fig. 5d). No changes in LC3-II protein level were observed even after the addition of CQ. Cells transfected with sham vector demonstrated elevated levels

of LC3-II after treatment with TTFields similar to U-87 MG wild-type cells (Fig. 5d left panel). Further validation using immunofluorescent staining revealed reduced prevalence of LC3 puncta in siAMPK-transfected cells relative to cells transfected with sham vector following 48 h of TTFields application (Fig. 5d right panel).

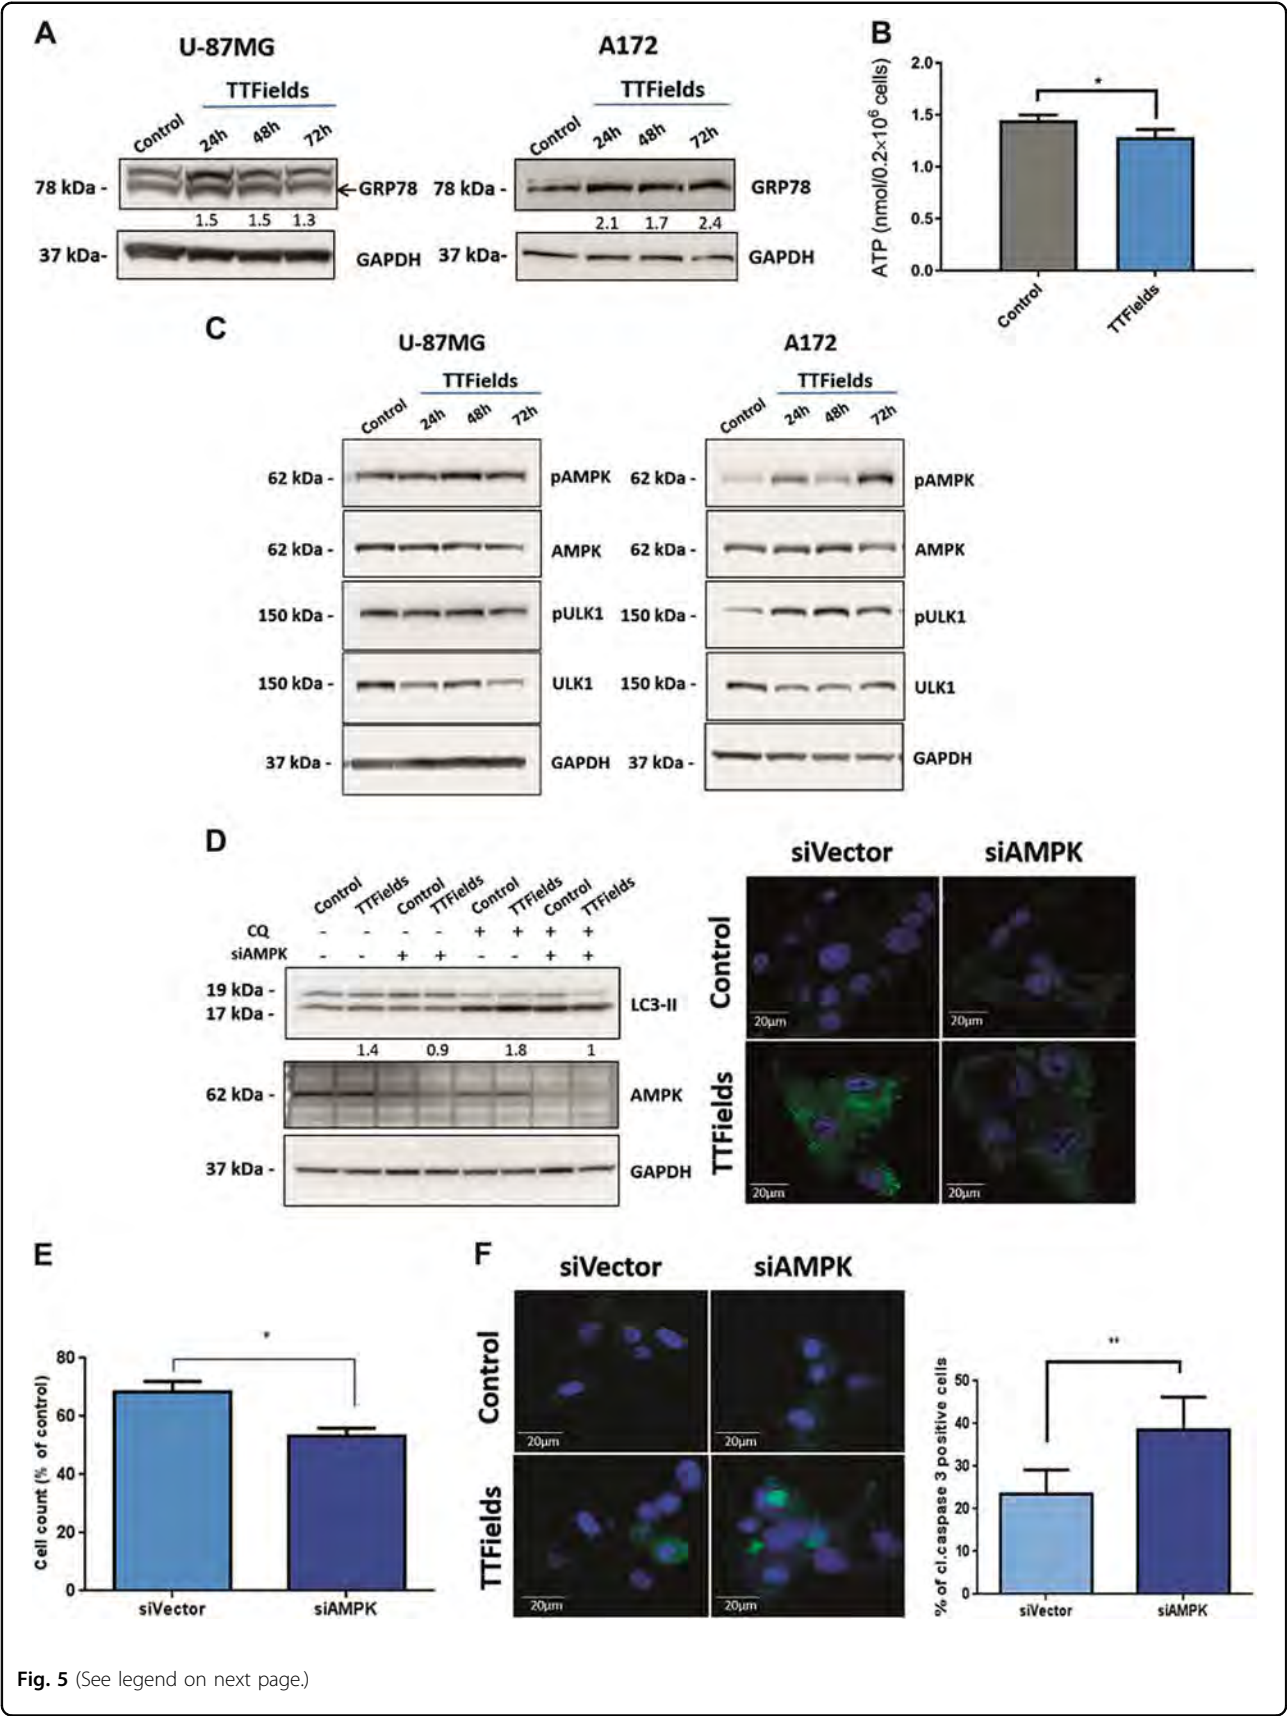

TTFields application for 48 h led to a significant reduction in the number of siAMPK cells relative to sham vector transfected cells (47% and 32% reduction in siAMPK and siVector, respectively) (Fig. 5e). The treated siAMPK cells demonstrated elevated levels of cleaved caspase-3 as seen by immunofluorescent staining (Fig. 5f).

Collectively, these results indicate that TTFields' upregulated autophagy is mediated through the AMPK pathway, and that inhibition of this pathway rendered the cells more susceptible to treatment.

#### Inhibition of autophagy enhances TTFields efficacy

TTFields-enhanced cytotoxic effect following AMPK silencing could be the outcome of an autophagy-independent processes, as AMPK regulates multiple

(see figure on previous page)

**Fig. 5 Induction of autophagy by TTFields is AMPK dependent.** **a** U-87 MG and A172 cells were either left untreated or were treated with TTFields for indicated time points. Immunoblot analysis of GFP78 protein. Numeric values represent the fold increase in GRP78 signal, normalized to loading control (GAPDH), relative to untreated control. **b** Quantification of intracellular ATP levels in U-87 MG cells either left untreated or treated with TTFields for 72 h. The results are presented as average ATP concentration (nmol/2 × 10<sup>6</sup> cells) from three independent experiments (\**P* < 0.01, Student's *t*-test). **c** U-87 MG and A172 cells were either left untreated or were treated with TTFields for indicated time points. Immunoblot analysis of pAMPK and pULK1 proteins. GAPDH was used as loading control. (5D-F) U-87 MG cells were transfected with AMPK-targeting siRNA (siAMPK) or with siRNA sham vector (siVector), and were incubated for 48 h with or without TTFields application. CQ 20 μM was added for the last 4 h of the treatment where indicated. **d** (left panel) Immunoblot analysis of LC3 and AMPK. Numeric values represent the fold-change in LC3-II signal, normalized to GAPDH signal, relative to respective control. **d** (right panel) CQ-treated cells were fixed and stained for LC3 (green) and DAPI (blue), original magnifications: × 40. **e** Cell count of siAMPK- or siVector-expressing cells after the TTFields treatment. (0.01 < \**P* < 0.05, Student's *t*-test, *n* = 3). **f** siVector- and siAMPK-transfected U-87 MG cells were either left untreated or were treated with TTFields for 48 h. Cells were then fixed and stained for cleaved caspase-3 (green) and DAPI (blue) (left panel). Images from each treatment were analyzed manually and the fraction of cleaved caspase-3 positive cells was calculated for at least 200 cells from each group (right panel) (\*\**P* < 0.01, Student's *t*-test, *n* = 2)

pathways. We utilized a genetic approach to specifically inhibit autophagy in cells using shATG7. Autophagy-related protein 7 (ATG7) is one of the key regulators of autophagosome formation and is responsible for conversion of LC3-I to LC3-II by phosphatidylethanolamine conjugation<sup>33</sup>. For this purpose, we generated lentiviral-mediated shATG7-expressing stable clones in U-87 MG and A172 cell lines. Inhibition of autophagy led to a significant decrease in cell numbers following 72 h of TTFields application relative to cells expressing sham vector (36% vs. 64% of cell reduction in shVector and shATG7 cells, respectively, in U-87 MG and 46% vs. 62% in A172) (Fig. 6a, Supplementary Figure 5). These results demonstrate that the inhibition of autophagy sensitizes glioma cells to TTFields treatment. Having established the necessity of autophagy for cell survival following TTFields application, we hypothesized that pharmacological targeting of autophagy could potentially provide a promising therapeutic strategy to circumvent resistance to TTFields. To test this, we combined TTFields with CQ in U-87 MG and A172 cells. We found that the combination treatment resulted in a significant reduction in cell numbers. Of note, this improvement in efficacy was observed even at low CQ concentrations (3 μM), whereas CQ monotherapy had no effect on cell counts (Fig. 6b). Flow cytometry analysis revealed higher levels of apoptosis (75%) in cells treated with TTFields in combination with low dose CQ (3 μM), whereas CQ monotherapy resulted in only 25% increase in apoptosis in A172 cells and 8% in U-87 MG cells (Fig. 6c). Overall, these findings suggest that glioma cells upregulate autophagy as a resistance mechanism to TTFields, and that pharmacological inhibition of autophagy circumvents this resistance and enhances the anti-mitotic effects of TTFields.

## Discussion

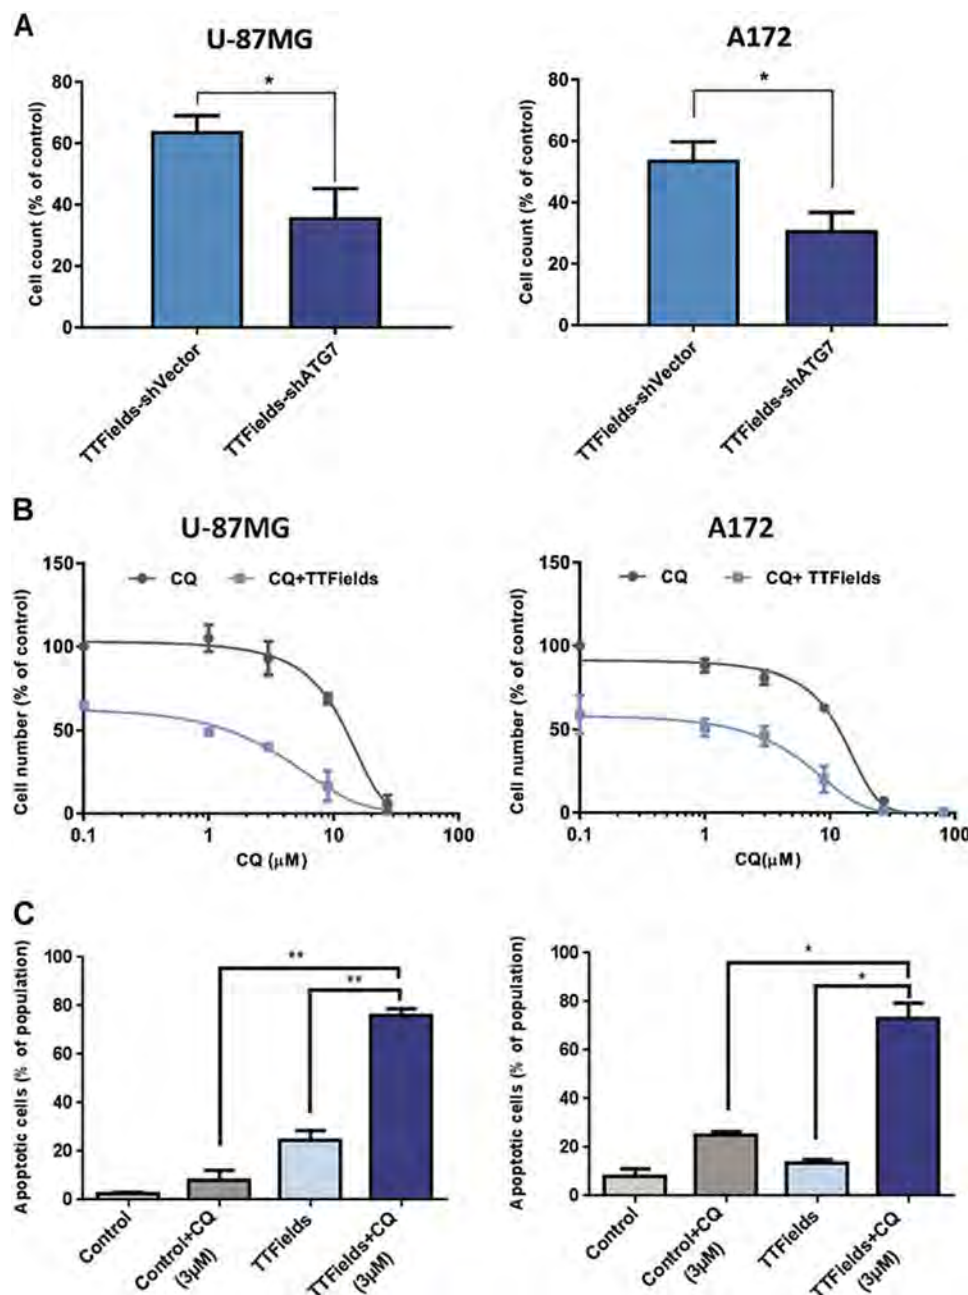

TTFields therapy is a physical treatment modality that has been demonstrated to improve both progression-free and overall survival in glioblastoma patients when added

to standard maintenance temozolomide chemotherapy<sup>4</sup>. Previous studies have demonstrated that TTFields exert an anti-mitotic effect by decreasing the fraction of polymerized tubulin during mitosis thus hampering normal spindle organization and producing severe structural mitotic deformities. These may lead to chromosome aneuploidy in the resulting daughter cells<sup>8</sup>. How cells survive the stress inflicted by TTFields is poorly understood. In this study, we demonstrate that daughter cells surviving TTFields application upregulate autophagy in response to proteotoxic stress, thereby promoting resistance to treatment (Fig. 7).

As TTFields act as a microtubule depolymerization agent, and as microtubules have an important role in both autophagosome transport and autophagosome-lysosome fusion, we speculated that the observed increase in autophagosome accumulation may result from interference in these processes, as demonstrated in cells treated with vinblastine (a known microtubule depolymerization agents)<sup>34</sup>. However, our results demonstrate successful autophagosomes-to-lysosome fusion under TTFields application, suggesting that such perturbation to the autophagy process is not inflicted by TTFields.

It is important to better understand how TTFields application promote autophagy in treated cells. It has been proposed that cells respond to aneuploidy by engaging proteotoxic stress response, which includes upregulation of pathways leading to the degradation of cellular constituents and protein folding<sup>30</sup>. Specifically, upregulation of autophagy was observed consistently in aneuploid cells<sup>28</sup>. We exploited single-cell analysis to show for the first time that TTFields application specifically triggers autophagy in the progeny cells that divided during treatment. This finding suggests that TTFields enhance autophagy in glioma cells as part of a cellular response to aberrant mitosis, with aneuploidy having a crucial role. Aneuploidy-induced proteomic change was previously shown to generate proteotoxic stress accompanied by

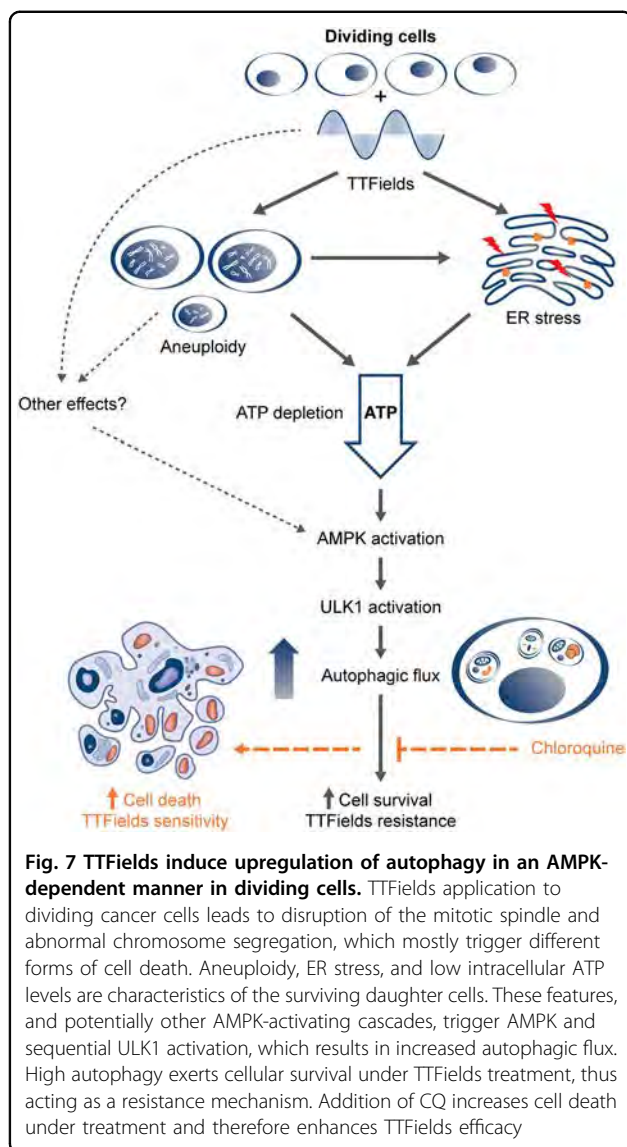

**Fig. 6** Autophagy inhibition triggers apoptosis and results in increased TTFIELDS efficacy in glioma cells. **a** U-87 MG and A172 were infected with lentiviral particle containing shATG7 or sham vector (shVector). Cells were then either left untreated or were treated with TTFIELDS for 72 h and enumerated by flow cytometry. The data are presented as percent of control. ( $0.01 < *P < 0.05$ , Student's *t*-test,  $n = 3$ ). **b**, **c** U-87 MG and A172 were treated for 72 h with CQ alone (1–27  $\mu$ M) and in combination with TTFIELDS. **b** Dose-response blots for U-87 MG (left) and A172 (right). **c** Fraction of apoptotic cells as indicated by Annexin V/7-AAD staining in TTFIELDS-treated vs. control cells, with or without CQ (3  $\mu$ M) ( $0.01 < *P < 0.05$ ,  $**P < 0.01$ , Student's *t*-test,  $n = 3$ )

additional energy requirements as reflected by low intracellular ATP levels<sup>29,30</sup>. We demonstrate that following TTFIELDS application, there is an increase in endoplasmic reticulum stress and reduced levels of intracellular ATP. Our data indicate that TTFIELDS-induced autophagy is

mediated and dependent on AMPK activity, which is in line with the observed proteotoxic stress response and reduced ATP intracellular levels, as AMPK is activated by low-energy status. Therefore, we propose that autophagy is triggered via AMPK activation in response to aneuploid

status following cell division under TTFIELDS application (Fig. 7).

It is noteworthy that Karanam et al.<sup>11</sup> have recently shown that TTFIELDS can potentially induce replication stress and reduction of BRCA1 pathway proteins, eventually leading to genotoxic stress.

Therefore, in addition to aneuploidy, AMPK-dependent induction of autophagy can also be potentially triggered by such genotoxic stress. For example, the serine/threonine kinase ATM, which is a major sensor of DNA double-strand breaks, can activate AMPK, thus leading to induction of autophagy<sup>35,36</sup>. Another example is the DNA damage repair enzyme PARP1, which is associated with elevated AMP levels that activate AMPK<sup>37</sup>. In the present study, we have not examined whether these pathways are activated following TTFIELDS application and future

studies are needed to assess the contribution of TTFIELDS-induced genotoxic stress to autophagy.

Induction of autophagy in normal tissue may exert a detrimental effect and lead to autophagic cell death<sup>38,39</sup>. Effective TTFIELDS intensities are present not just in the tumor but also in the surrounding tissues and may potentially affect normal bystander cells. However, both preclinical and clinical evidence did not reveal adverse events in normal tissues. Our findings demonstrate that the upregulation of autophagy by TTFIELDS is restricted to dividing cells, which may explain the relatively lack of safety issues with this modality.

Extensive preclinical evidence for the involvement of autophagy in cancer cell survival has led to a rise in clinical trials, which are underway to evaluate the therapeutic potential of autophagy inhibitors in combination with chemotherapy<sup>18,40,41</sup>. A preclinical glioma model showed that autophagy upregulation in response to temozolomide confers resistance to treatment<sup>42</sup>. Although TTFIELDS differ significantly in their mode of action from chemo and radiotherapy, our data indicate a similar resistance pattern of cells utilizing autophagy to evade lethal effects. Specifically, our results demonstrate that blocking autophagy induced by TTFIELDS by using either genetic or pharmacologic approaches, results in increased treatment efficacy. CQ and its derivative hydroxychloroquine, a broadly used anti-malarial agent, are currently the only clinically available drugs to inhibit autophagy<sup>43</sup>. In our study, combination of TTFIELDS with CQ resulted in decreased cell viability in a dose-dependent manner. Moreover, the presence of low concentration of CQ, which has no effect on cell number as a monotherapy, resulted in high levels of apoptosis when combined with TTFIELDS (Fig. 7). These results indicate increased treatment efficacy for the combined treatment and provide strong rationale for additional in-vivo studies.

Interestingly, a recent study by Silginer et al.<sup>17</sup> demonstrated that the concomitant use of 3-Methyladenine (3-MA; early-stage inhibitor of autophagy) during TTFIELDS application result in higher cell viability. 3-MA is known to block class I and class III PI3K activity, thus exhibiting dual activity that could lead to either inhibition or upregulation of autophagy<sup>44</sup>. Targeting a complex process such as autophagy may lead to different consequences depending on the exact stage of autophagy being targeted. It has been reported that in treatment regimens utilizing cytotoxic drugs combined with agents that inhibit autophagy at an early stage, the cytotoxic effect was hindered. On the other hand, inhibition at late stages in autophagy (e.g., using bafilomycin or CQ) led to enhanced efficacy of the same treatment as reflected by increased cytotoxic effect, suggesting that accumulation of autolysosomes is necessary for cell death induction<sup>45,46</sup>. Although CQ is primarily acknowledged as

blocker of lysosomal degradation, a recent study by Mauthe et al.<sup>47</sup> demonstrated that CQ can also inflict severe disorganization of the Golgi and endo-lysosomal systems. Therefore, it is imperative to also acknowledge the autophagy-independent effects of CQ and the possibility that some elements of the enhanced treatment efficacy of the combined treatment with CQ may be attributed to other autophagy-unrelated cellular alterations.

The combination of CQ with two additional drugs, 17-allylamino-17-demethoxy-geldanamycin and 5-aminoimidazole-4-carboxamide riboside, had been shown to promote proteotoxic and metabolic stress leading to the induction of apoptosis exclusively in aneuploid cells<sup>27</sup>. Future work is warranted on these and other therapeutic combinations that could leverage the stress response induced by TTFields, to further enhance treatment efficacy.

## Materials and methods

### Cell lines and cultures

All cell lines were obtained from ATCC: MSTO-211H (human biphasic mesothelioma), KLN-205 (murine squamous cell carcinoma), LLC-1 (murine Lewis lung carcinoma), AsPC-1 (pancreatic adenocarcinoma), A172, U-87 MG, LN229 (human glioma cell lines), and F98 (rat glioma). Cells were cultured in Dulbecco's modified Eagle's medium (Biological Industries) or RPMI (GIBCO) medium supplemented with 10% fetal bovine serum and antibiotics.

### TTFields application

TTFields were applied to cell cultures using the inovitro™ system (Novocure Ltd) as described<sup>48,49</sup>. Cells were seeded on cover slips at a density of 5000–20,000 cells in 500 µL and treated at predetermined optimal frequencies: MSTO-211H (150 kHz), KLN-205 (150 kHz), LLC-1 (150 kHz), AsPC-1 (150 kHz), A172 (200 kHz), U-87 MG (200 kHz), LN229 (200 kHz), and F98 (200 kHz) at the same nominal intensity (1.75 V/cm RMS). TTFields were applied from two directions, which were changed by 90° every 1 s as previously described<sup>3</sup>. Culture media (2 ml per dish) was replaced every 24 h for all control and treatment dishes.

### Flow cytometry

To assess cellular granularity, cells treated with TTFields for 72 h were analyzed based on their side-scatter values. Evaluation of treatment efficacy was quantitatively determined by cell count after specified treatment duration. The relative number of cells at the end of treatment was expressed as a percentage of untreated control. For detection of apoptosis, cells were double-stained with fluorescein isothiocyanate-

conjugated Annexin V (MEBCYTO 4700 Apoptosis Kit; MBL) and 7-Aminoactinomycin D (BioLegend) as per the manufacturer's instructions. Data acquisition was obtained using iCyt EC800 (Sony Biotechnology) flow cytometer.

### LysoTracker staining

Cells were stained for 80 min in 37 °C with 75 nM LysoTracker probe (Molecular Probes). Images were obtained using upright motorized microscope with × 40/0.75 objective (ZeissAxio Imager Z2) equipped with the Orca R2 camera (Hamamatsu Photonics, Japan).

### Immunocytochemistry

For autophagy assessments, cells were grown on glass cover slips and treated using the inovitro™ system (Novocure, Israel) for 48 h. At the end of the treatment, cells were fixed with ice-cold methanol for 10 min. The cells were then serum-blocked and stained with microtubule-associated protein 1 LC3 (rabbit polyclonal, Novus) and LAMP1 antibody (mouse monoclonal, Santa Cruz). Alexa Fluor 488- or 533-conjugated secondary antibody was used (Jackson ImmunoResearch). DNA was stained with the dye 4',6-diamidino-2-phenylindole (DAPI) (Sigma-Aldrich) at 0.2 µg/ml for 20 min. Images were collected using a LSM 700 laser scanning confocal system, attached to an upright motorized microscope with × 63/1.40 oil objective (ZeissAxio Imager Z2). To better detect LC3 by immunofluorescence, cells were cultured in the presence of CQ diphosphate (Sigma) (CQ, 20 µM) during the last 3 h of the treatment. CQ was applied to both control and TTFields-treated cells. Colocalization of LAMP1 and LC3 was tested in three individual cells from each treatment using the profile tool in the Zen 2.3. software (Blue edition; Carl Zeiss Microscopy, GmbH). Areas in which at least two LC3 foci were apparent were used for the analysis. For cleaved caspase-3 staining following treatment, cells were fixed with paraformaldehyde (PFA) 4%, permeabilized with 0.3% Triton solution in phosphate-buffered saline (PBS) (× 1), and stained with anti-cleaved caspase-3 antibody (rabbit polyclonal, Cell Signaling). The quantification of intensity of green signal, reflecting amount of LC3-positive puncta, was carried out using ImageJ software and presented as percentage of average intensity per cell normalized to average intensity in untreated cells. The quantification of cleaved caspase-3-positive cells was done manually in a blinded manner. The data were presented as percent of positive stained cells.

### Cell lysates and immunoblotting

Cell extracts were prepared using RIPA lysis buffer containing 150 mM sodium chloride, 1% NP-40, 0.1% SDS, 50 mM Tris pH = 8, supplemented with a cocktail of

protease (Complete Mini, Roche), and phosphatase inhibitors (Thermo Scientific). After determining protein concentration (Bradford reagent, Bio-Rad), 30 µg protein were resolved by SDS-polyacrylamide gel electrophoresis under reducing conditions. After electrophoresis, proteins were transferred to polyvinylidene difluoride membrane (Bio-Rad) and probed with the appropriate primary antibody: LC3 (NB600-307) purchased from Novus, pAMPK (2535), AMPK (2793), pULK1 (12753), ULK1 (8054), pP70 (9205s), ATG7 (8558) from Cell Signaling; GAPDH (SC-32233), GRP78 (BiP) (SC-376768) from Santa Cruz; Vinculin (V9131) from Sigma-Aldrich followed by horseradish peroxidase-conjugated secondary antibody (Abcam ab6721, ab97023), Rockland (111-035-144), and a chemiluminescent substrate (Millipore).

#### siRNA-mediated knockdown of Ampk

U-87 MG cells were transfected with siRNA specific for Ampk (SMARTpool: ON-TARGETplus Human PRKAA1 siRNA, Dharmacon) using Lipofectamine (Invitrogen, Life Technologies Corporation) according to the manufacturer's instruction. Cells were seeded on cover slips in invitro dishes 24 h before transfection. At the time of the experiment, the cells had reached 50% confluency. The culture medium was replaced with Opti-MEM (Invitrogen) containing 20 nM of siRNA mixed with 1 ml of Dulbecco's Modified Eagle antibiotics-free medium and 10 µl of RNAi-Lipofectamine 2000. After 48 h, dishes were connected to the invitro systems and TTFIELDS were applied for 48 h.

#### Time-lapse microscopy

U-87 MG cells were transfected with pSELECT-GFP-hLC3 vector (InvivoGen) using Lipofectamine (Invitrogen, Life Technologies Corporation) according to the manufacturer's instruction. Following transfection, cells were washed and selected for resistance to zeocin (600 µg/ml) (InvivoGene). Stable transfected cells were observed for 24 h using time-lapse series microscopy (ZeissAxio Observer; × 10 objective) either with or without TTFIELDS. TTFIELDS (1.75 V/cm) were applied using the invitro Live™ system (Novocure). Briefly, two pairs of transducer arrays were printed perpendicularly on the outer walls of a cylinder invitro Live insert composed of high dielectric constant ceramic [lead magnesium niobate–lead titanate]. The transducer arrays were connected to a sinusoidal waveform generator that generated the electric fields in the medium. The orientation of the TTFIELDS were switched 90° every 1 s, thus covering the majority of the orientation axis of cell divisions as previously described by Kirson et al.<sup>3</sup>. Temperature was measured by 2 thermistors (Omega Engineering, Stamford, CT) attached to the ceramic walls. Cells were grown in high Glass Bottom 35 mm µ-Dish (Ibidi, GMBH). The invitro Live insert

was placed inside the glass bottom dish. Image stacks were acquired every 15 min.

#### Time-lapse microscopy data analysis

Single cells were followed manually by two independent investigators. Mitotic events were recorded in a blinded manner. Images of cells before and after mitosis were analyzed using ImageJ software (NIH) as described by Veldhoen et al.<sup>50</sup>, and modified to accommodate single-cell analysis. Briefly, puncta were identified by generating surfaces in ImageJ after background subtraction (Rolling Ball Background, rolling = 20) and setting of identical threshold to all images. The fluorescence intensity localized to all puncta in each cell after mitosis were divided by the fluorescence intensity measured in the same cell before mitosis. A threshold value of twofold increase in LC3-GFP fluorescence intensity relative to the initial state of the cell was defined as “increased.” For non-dividing cells, images from the beginning and the end of treatment were analyzed and compared in the same manner.

#### Electron microscopy

A172 and U-87 MG cells, control or treated with TTFIELDS for 48 h, were fixed in PFA (3%) + glutaraldehyde 2.5% + 0.1 M cacodylate buffer + 5 mM CaCl + 3% sucrose and further processed for blocking and section preparation. Thin sections (70 nm) were coated with carbon and visualized using Zeiss Ultra-Plus FEG-SEM equipped with transmission electron detector, at acceleration voltage of 30 kV. In addition, U-87 MG cells control or treated, in the presence of CQ (1 µM, 24 h) (Sigma-Aldrich), were fixed as described and were visualized using JEOL JEM-1011 TEM. Count of autophagic vacuoles was performed manually in a blinded manner.

#### shRNA lentiviral infection

Human ATG7 short hairpin RNA (shRNA) and non-silencing-GIPZ lentiviral shRNAmir control were purchased from Dharmacon. shATG7 containing viral particles were produced using LENTI-Smart kit (InvivoGen), according to the manufacturer's instruction, in 293T cells. U-87 MG and A172 cells were infected with lentiviral particles; 24 h after infection, cells were washed and selected for puromycin (Sigma) (2 µg/ml) resistance for 3 days. ATG7 protein levels in stable culture were further validated in western blot analysis with specific anti ATG7 (rabbit monoclonal, Cell Signaling) antibody.

#### ATP measurement

ATP intracellular levels were measured with colorimetric ATP assay kit (Abcam) according to the manufacturer's instructions. After 48 h of treatment, cells were collected and  $1 \times 10^6$  cells from each sample were resuspended in ATP lysis buffer. Trichloroacetic acid (100%)

was used for sample deproteinizing followed by neutralization step KOH (1 M). ATP reaction mix and background control (50  $\mu$ L) was added to the wells and incubated for 30 min in dark, followed by an absorbance measurement at 550 nm using an ELISA reader (infinite F200, Tecan).

### In-vivo application of TTFields

All animal studies were approved by the Novocure Internal Animal Care Committee in accordance with the Technion-Israel Institute of Technology guidelines for the care of laboratory animals. Twelve-week-old Male Fischer rats (Harlan Laboratories, Israel) were inoculated stereotactically into the subcortical white matter in the right hemisphere with glioma (F98) cells ( $1 \times 10^4$ ), as previously described<sup>2</sup>.

Rats were allowed to recuperate for 7 days before treatment initiation. Application of TTFields (200 kHz) to the rat brain was initiated 7 days after intracranial tumor inoculation and was maintained for 7 days. Two pairs of electrodes, each composed of two disks with a radius of 3 mm, were attached to the rat skull in dorsolateral and left–right positions generating two different field directions. The capacitance of each disk was about 30 nF. Each disk contained a thermistor in order to allow for constant temperature monitoring. The current source output was switched, every 1 s, between the two electrodes. Control rats were treated by means of sham electrodes, which were geometrically matched to the TTFields group. The Sham heat electrodes produced equal temperature changes to those produced by the field electrodes by means of a heating resistor incorporated within them. Each rat was placed inside a separate cage and the electrodes were connected to the NovoTTF-100A<sup>TM</sup> device. Rats were checked twice daily for their physical condition. At the end of treatment, the rats were killed and the tumors were removed.

### Immunohistochemistry

For immunofluorescent staining, paraffin-embedded tumor sections were deparaffinized with HistoChoice (Sigma-Aldrich) and rehydrated with graded alcohol treatments. Antigen retrieval was carried out by microwave treatment for 22 min in citrate buffer (pH 6.0). Sections were blocked in 10% normal goat serum in PBS and incubated overnight with primary antibody (LC3, Novus) following secondary antibody (Alexa Flour 488, Jackson ImmunoResearch) incubation and DAPI for nuclei counterstaining. The whole slide image was collected using Automatic slide scanner 250 Flash (3DHIS-TECH). The quantification of intensity of green signal, reflecting amount of LC3 staining, was carried out using CaseViewer following ImageJ software. Three different areas of similar size from each image were chosen in a

blinded manner to be analyzed by ImageJ software. Average green intensity per image was calculated. The data are presented as average intensity relative to control in each set of staining.

### Statistical analysis

Data are presented as means  $\pm$  SE. Statistical significance was analyzed by the two-tailed Student's *t*-test.  $\chi^2$ -analysis was applied to determine significant relationship between mitosis and TTFields treatment (GraphPad Prism 6 utility software). Values of  $P < 0.05$  were considered significant. All experiments were repeated at least three times with similar results.

# Dosimetric impact of tumor treating field (TTField) transducer arrays onto treatment plans for glioblastomas – a planning study

Christoph Straube<sup>1,2\*</sup> , Markus Oechsner<sup>1</sup>, Severin Kampfer<sup>1</sup>, Sophia Scharl<sup>1</sup>, Friederike Schmidt-Graf<sup>3</sup>, Jan J. Wilkens<sup>1,4</sup> and Stephanie E. Combs<sup>1,2,4</sup>

## Abstract

**Background:** Tumor-Treating Fields (TTFields) are a novel treatment strategy for glioblastoma (GBM) that is approved for the use concomitantly to adjuvant chemotherapy. Preclinical data suggest a synergistic interaction of TTFields and radiotherapy (RT). However, the dosimetric uncertainties caused by the highly dense arrays have led to caution of applying the TTF setup during RT.

**Methods:** In a RW3 slab phantom we compared the MV- and kV-CT based planned dose with the measured dose. VMAT-plans were optimized on MV-CTs of an Alderson head phantom without TTF arrays and then re-calculated on the same phantom equipped with TTF arrays. Dose at organs at risk (OAR) and target volumes (PTVs) were compared.

**Results:** Measurements at a depth of 2, 3 and 4 cm of a RW 3 slab phantom show an attenuation due to TTField arrays of 3.4, 3.7 and 2.7% respectively. This was in-line with calculated attenuations based on MV-CT (1.2, 2.5 and 2.5%) but not with the attenuation expected from kV-CT based calculations (7.1, 8.2 and 8.6%). Consecutive MV-CT based VMAT planning and re-calculation reveals, that the conformity and homogeneity are not affected by the presence of TTField arrays. The dose at organs at risk (OAR) can show increases or decreases by < 0.5 Gy, which should be considered especially in cases next to the skull base.

**Conclusion:** MV-CT based dose calculation results in reliable dose distributions also in the presence of TTField arrays. There is a small but clinically not relevant interaction between the TTField arrays and VMAT dose application. Thus, daily replacement of TTField arrays is not necessary in regard to deeply located OARs. RT is feasible, when a VMAT treatment plan is optimized to an array free planning CT. As the biologic effect of a concomitant treatment especially on OARs is currently unknown, a concomitant treatment should be performed only within clinical trials.

## Background

Alternating electric fields (tumor-treating fields, TTFields) are a novel treatment strategy for several malignancies, which has shown a stand-alone efficacy comparable to chemotherapeutic agents in recurrent glioblastoma (GBM) [1]. Also in primary GBM a significant benefit for patients treated with TTFields as a concomitant treatment during adjuvant chemotherapy is evident [1–3]. Based on these

results, the Optune® system (Novocure) gained FDA approval for the treatment of recurrent GBM in 2011 and for the treatment of newly diagnosed GBM in 2015 [4]. In Europe, Optune gained a CE certification in 2015. Furthermore, TTFields were included into the NCCN guidelines for the treatment of primary as well as recurrent GBM as one treatment option [5].

The pathophysiological background of TTFields is still under investigation. However, a prolongation of the cell division, probably elicited by the interference of the alternating electric fields with the condensation of polar tubulin molecules leading to an interruption in spindle formation, seems to be one hallmark of the effect [2, 4, 6, 7]. As a consequence, cells that are exposed to TTFields accumulate

within the G2/M-phase; notably, this phase is also associated with a significant vulnerability for radiation induced DNA damages [4, 7]. Besides differences between the proliferation rates of normal tissue cells and tumor cells, TTFIELD effects were described to be frequency dependent [2]. A theoretical synergistic effect of radiation and TTFIELDS was recently corroborated by the results of several preclinical studies, investigating the efficacy of a concomitant treatment with radiation and TTFIELDS in lung cancer and GBM cell lines [6–8]. The increased rate of cell death reported by these articles was explained by an impairment of double-strand break repair, the down-regulation of angiogenesis and invasion—related markers such as VEGF and MMP9 also point towards an impaired migration [6, 8]. Furthermore, within the context of chemotherapies, an earlier onset of effective treatments has shown an advantage over use of these therapies within a salvage treatment in low grade glioma as well as in GBM and Medulloblastoma [9–12].

When a synergistic effect of TTFIELDS and radiation seems to be possible, the mode of practically combining these modalities should be investigated. Generally spoken, there are two options of combining a radiotherapy to a TTFIELD treatment. First of all, one could detach the TTFIELD arrays before each fraction and re-attach a new set of arrays afterwards. This strategy would rule out any influence of the TTFIELD arrays onto the dose distribution and an increase of the dose at the organs at risk. On the other hand, a daily change of the arrays could lead to skin irritation and might be associated with longer intervals of de-activated TTFIELDS, with possible negative effects of its efficacy [13]. Additionally, increasing the frequency of array-changes would increase the costs, too. Another strategy would be to leave the arrays attached to the skull during radiotherapy. This strategy could be associated with an increased skin toxicity due to a previously prescribed bolus effect [14]. On the other hand, avoiding to change the arrays on a daily basis could increase the treatment compliance and would possibly reduce the treatment costs. Furthermore, since the TTFIELD transducer arrays consist of materials with a high physical density, there was considerable concern that array application during RT might influence the dose delivery to the patient. Additionally, image artefacts could interfere with the re-positioning of patients. Therefore, before any study concepts with RT and concomitant TTFIELDS are initiated, we focussed to determine any potential interactions between TTFIELD arrays and RT in terms of calculated dose and dose distribution.

## Methods

We first performed a planning study using RW3 water equivalent slabs as a phantom (PTW GmbH, Freiburg, Germany). The phantom was equipped with and without a

Novocure Optune TTFIELD array. TTFIELD arrays consist of 9 transducer arrays which each have a thickness of 2.5 mm, a diameter of 2 cm and a physical density of 7.75 g/cm<sup>3</sup>. The electron density (ED) of the arrays as well as the exact chemical composition is unknown. The whole setup was scanned with a Somatom Emotion CT-scanner (kV-CT, 1 mm slice thickness, voxel size 1 × 1 × 1 mm<sup>3</sup>, 130 kV; Siemens Medical Solutions, Erlangen, Germany) and with a TomoTherapy using its MV-CT function (2 mm slice thickness, voxel size 2 × 0.8 × 0.8 mm<sup>3</sup>, 3.5 MV; Accuray Inc., Sunnyvale CA, USA). Irradiation of the RW3 slab phantom was simulated with the treatment planning system (TPS) Eclipse 13.0 (Varian Medical Systems, Palo Alto, CA, USA) using an 0°, 15 × 15 cm<sup>2</sup>, 6 MV photon field with 200 MU. Hounsfield units (HU) were converted to ED based on two different HU-ED conversion tables, then calibrated for the MV-CT and the kV-CT, respectively. We are using kV- as well as MV-CT based treatment planning, the latter one for instance in cases with both sided hip replacements, within the daily clinical routine at our facility. The dose was calculated based on the kV-CT and the MV-CT of the phantom with the AAA13 algorithm. No additional density correction was applied to correct for artefacts or the density of the TTFIELD arrays.

The calculated dose was compared to measurements from irradiating an identical field (15 × 15 cm<sup>2</sup>, 6 MV, 200 MU) to the RW3 slab phantom with and without a TTFIELD array. Measurements were performed on a Trilogy linear accelerator (Varian Medical Systems, Palo Alto, CA, USA). The dose at 2, 3 and 4 cm depth was detected by a 2D diode detector array (MapCheck2, SunNuclear Corp., Melbourne, FL, USA). In all measurements, the TTFIELD device was not connected to a field generator when radiation was applied, as effects of the fields on secondary electrons currently cannot be estimated within any planning system and as a radiation induced damage of the portable field generator cannot be excluded. Therefore, only the passive effect of the TTFIELD arrays can be presented. Each measurement included three technical replicates. The attenuation caused by the TTFIELD arrays was calculated as ratio between the dose without the arrays and the dose with the arrays attached to the uppermost RW3 slab. The attenuated dose was measured within the 71 diodes directly below the TTFIELD arrays and was compared to 71 reference points in the same position of the treatment plans. A difference between measurements and dose calculations of < 3% was deemed to be clinical acceptable.

According to the treatment recommendation of TTFIELDS, the position of the TTFIELD arrays have to be changed every 3 days in order to reduce skin irritations caused by the contact gel below the electrodes. To account for this, the Alderson head-phantom was first scanned with kV-CT and MV-CT without the TTFIELD arrays, and thereafter with four TTFIELD arrays in two different positions (Position “A”

and “B”). Each setup included four TTField transducer arrays, with two arrays in opposing positions (i.e. anterior-posterior) while the two remaining arrays were positioned orthogonally (i.e. bi-temporal) (Additional file 1: Figure S1).

Two target volumes were generated to investigate for two distinct questions. PTV1 would have represented a parietal glioblastoma, a location where almost the entire PTV lies within CT slices that are covered by a large number of electrodes. This volume was chosen to investigate whether the electrodes would lead to impairments within the dose distribution to the target volume. PTV2 simulates a temporopolar glioblastoma. Due to its position next to the skull base, irradiation of such volumes often is a trade-off between the dose coverage of the PTV and the dose of the organs at risk, namely the optical nerves, the chiasm and the brainstem. This volume was chosen to investigate, whether the addition of electrodes could lead to an overdosing within the OARs. The effect on the dose distribution caused by the electrodes applied to the head was evaluated by optimizing volumetric arc treatment plans (VMAT) with two arcs with 6 MV for the two PTVs on the MV-CT of the Alderson phantom without electrodes. Subsequently, this plan was copied and recalculated onto MV-CTs of the Alderson phantom with four TTField arrays placed onto the head in position A and B, corresponding to the clinical use of the arrays. The amount of monitor units (MU) was identical for all three plans. The resulting dose distributions were compared according to the ICRU 83 report recommendations by comparing conformity (defined as  $CI = V_{95\%}/PTV$ ), homogeneity (defined as  $HI = (D_{98\%} - D_{2\%})/D_{50\%}$ ),  $D_{min}$ ,  $D_{98\%}$ ,  $D_{mean}$ ,  $D_{50\%}$ ,  $D_{2\%}$ ,  $D_{max}$  of the PTV as well as according to the  $D_{mean}$ ,  $D_{max}$ ,  $D_{2\%}$ ,  $V_{50Gy}$  and  $V_{54Gy}$  of the OARs [15].

To investigate the impact of the TTField arrays on image quality and registration, we compared kV-CTs, MV-CTs and kV cone beam CTs (CBCT) of the Alderson head phantom with TTField arrays. The latter was acquired using the kV on-board imaging system of the Varian Trilogy.

## Results

### RW3 slab phantom

kV-CT based scanning results in significant artefacts within the slices involving the arrays. Due to their high physical density the mean CT-value of the arrays is 3069 HU (SD 1.1), which is limited due to the maximum representable HU value of 3071 HU in our kV-CT scanner. The images were affected by several artefacts, including a feigned thickness of 7 mm and a large halo below and above the arrays onto which a CT-Value of > 1000 HU is projected (Fig. 1a, right panel).

MV-CT-scanning resulted in almost artefact free images (Fig. 1a, left panel). The TTField transducer arrays were

represented by a mean density of 2437 HU (SD 134) and were depicted slightly thicker than real (3.6 mm) but with an accurate structure. The difference in thickness, however, can also be caused by the lower z-resolution of the MV-CT.

Comparing the dose calculated on the RW3 slab phantom with and without TTField array to the doses measured in 2, 3 and 4 cm of depth, kV-CT calculation resulted in a dose attenuation by the electrodes of 7.1, 8.2 and 8.6%. The dose calculation based on the MV-CTs resulted in an attenuation of 1.2, 2.5 and 2.5% in 2, 3 and 4 cm, respectively. The dose measurement of the same setup in the same depths with the MapCheck2 diode array resulted in an attenuation of 3.4, 3.7 and 2.7% (Fig. 1b, Table 1). When the doses at 2, 3 and 4 cm of MV-CT based or kV-CT based calculations were compared to the measured doses at the specific depths, this resulted in a difference of 2.2, 1.1 and 0.05% or – 4.2, – 5.0 and – 6.9%, respectively.

A 5 mm area below the electrodes showed an increase in the local dose by 23.7% ( $D_{mean}$ ) and 1.0% ( $D_{max}$ ) for MV-CT and 10.4% ( $D_{mean}$ ) and 3.3% ( $D_{max}$ ) for kV-CT, respectively, indicating a bolus effect of the electrodes. This changes could not be verified with the MapCheck2 system, as the minimum depth for measurements with this system is 2 cm.

### Alderson head phantom

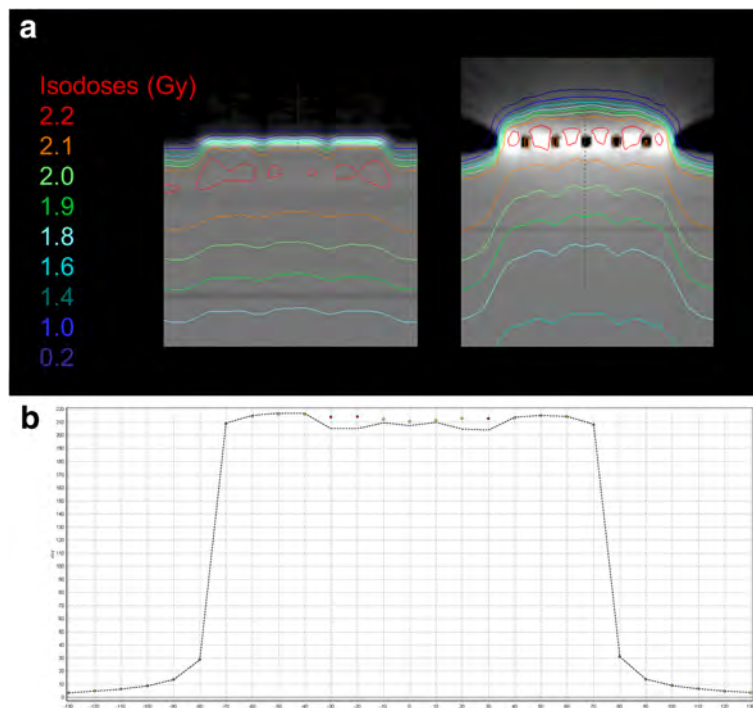

As expected from the results from the RW3 slab phantom scans, kV-CTs and CBCTs of the head phantom suffered from a large burden of artefacts in the slices that involved electrodes (Fig. 2). Due to the higher photon energy there were almost no artefacts present in the MV-CT. Bony structures from the skull base were clearly visible in all modalities. When the registration was based on the bony structures of the phantom, including the skull base, registration of the images was not affected by the presence of the TTField arrays.

In both PTVs, the addition of TTField arrays led to a negligible reduction of the conformity and minor changes of the mean and maximum dose up to 1.0 Gy (Figs. 3 and 4, Tables 2 and 3). In the presence of TTField arrays,  $D_{min}$  was up to 4.4 Gy lower as compared to plans without TTField arrays. The volume compromised by this decrease had a size of 0.05 cm<sup>3</sup>. No changes in the homogeneity of the dose distribution were found. The OARs, namely the optical nerves, the chiasm and the brainstem, were mostly stable or decreased (Tables 2 and 3). The largest increase was observed at the optic nerves, where an increase of up to 0.4 Gy was present.

## Discussion

In the present work, we used MV-CT based treatment planning and re-planning to investigate changes in the

**Fig. 1** **a** MV-CT (left side) and kV-CT (right side) of a RW3 slab phantom equipped with a NovoCure Optune TTField array planned for a  $15 \times 15$  cm<sup>2</sup> 0° 6 MV 200 MU photon beam. **b** For verification of the dose calculation, the dose in 2 cm depth was measured in the same setup with and without a TTField array at the surface of a RW3 slab phantom. The dots represent the measurement without the TTField array, the dashed line represents the measurements with TTField

dose delivery introduced by high density TTField arrays. This information is prerequisite for establishing study protocols that can investigate the safety and efficacy of a concomitant use of TTFields during a course of radiotherapy.

We used the AAA13 algorithm to calculate the dose distributions. This algorithm is based on electron densities which previously have to be converted from the HU

values of kV or MV-CTs. This is done by conversion tables that correlate HU values and electron densities [16]. The conversion tables are derived from scans of different materials with known electron densities and are machine-specific. We use distinct conversion tables for MV-CT based dose calculations within our daily routine, especially when patients with hip-replacements have to be treated within the pelvic area.

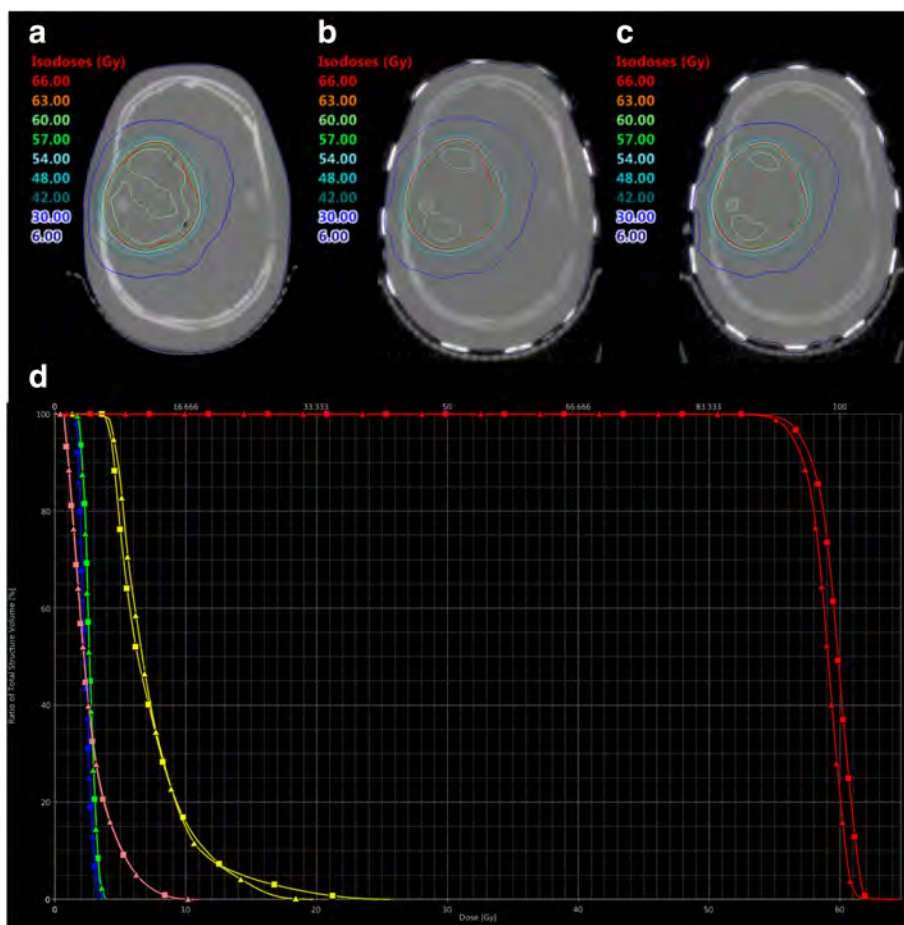

**Table 1** Comparison of the calculated to the measured doses in 2, 3 and 4 cm depth of a RW3 slab phantom. All experiments were performed with a Trilogy linear accelerator irradiating a 6 MV,  $15 \times 15$  cm<sup>2</sup> field with 200 MU. The doses were measured on 71 points directly below the TTField arrays with a MapCheck2 2D diode detector array. The arithmetic average as well as the standard deviation of the doses at these 71 measure points are presented

	depth	Without TTField arrays		With TTField arrays		Attenuation
		Average (cGy)	StdDev	Average (cGy)	StdDev	
kV	2 cm	214.3	1.10	199.1	4.90	7.09%
	3 cm	204.6	0.80	187.9	4.90	8.16%
	4 cm	194.3	0.60	177.6	4.70	8.59%
MV	2 cm	214.4	0.80	211.9	1.20	1.17%
	3 cm	204.6	0.60	199.5	1.20	2.49%
	4 cm	194.8	0.50	189.9	1.20	2.52%
Phantom	2 cm	214.6	1.60	207.4	4.00	3.36%
	3 cm	204.9	1.30	197.3	3.40	3.71%
	4 cm	195.0	1.10	189.8	4.20	2.67%

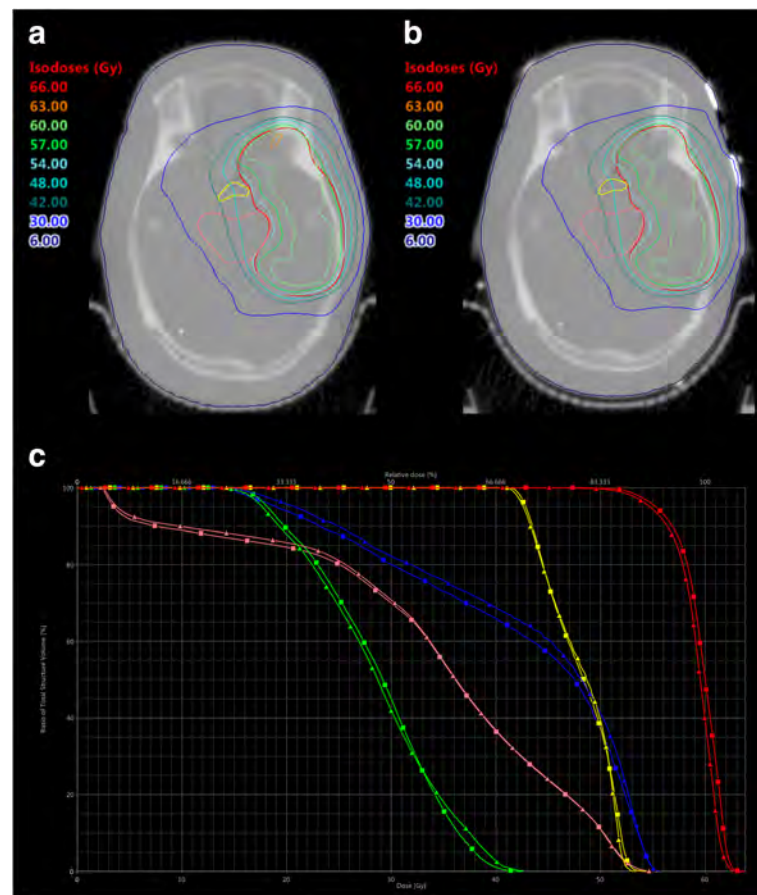

**Fig. 2** kV-CT (a), CBCT (b) and MV-CT (c) of an Alderson head phantom equipped with TTField transducer arrays (Range – 1000 to 3071 HU). In kV-CT and CBCT, bony structures are only visible when they are not within the direct vicinity of TTField arrays and streaky artefacts are present. In contrast, MV-CT is almost free of artefacts, all bony structures are clearly visible and also structures with a low radiographic density, i.e. bore holes, are resolved.

**Fig. 3** MV-CTs of an Alderson head phantom without (a) and with TTField arrays in position A (b) and B (c). A treatment volume resembling the PTV for a parietal glioblastoma was optimized to the MV-CT in (a) and re-calculated to MV-CT (b) and (c). **Fig. 4** MV-CTs of an Alderson head phantom without (a) and with TTField arrays (b). A treatment plan for a target volume resembling the PTV for a temporopolar glioblastoma was optimized on the MV-CT in (a) and re-calculated to MV-CT (b). c shows a DVH-comparison between the plan for (a) (squares) and (b) (triangles). Red: PTV, yellow: chiasm, blue: left optical nerve, green: right optical nerve, pink: brainstem

The presence of high density materials, such as TTField arrays with a physical density of  $7.75 \text{ g/cm}^3$ , can lead to photon starvation that propagate to streak artefacts [17]. These artefacts are consequently represented by apparently high, in most cases maximum, HU values. In our case, the arrays as well as parts of the halo were represented by up to 3071 HU with kV-CT, corresponding to a relative electron density of 2.52. This value is lower than expected from the physical density, however, the true ED of the arrays is unknown. Furthermore, due to the artefacts, the thickness of the arrays is seemingly bigger (7 mm in kV-CT as compared to 2.5 mm of physical thickness). Altogether, artefacts in general and also in our special case lead to an impaired accuracy of the dose calculation [18]. This effect can be impressively seen in case of the kV-CT based dose calculation in Fig. 1a.

CT images that are based on higher energy photons, such as our MV-CTs with 3.5 MV, are less prone by artefacts. This is due to the energy dependence of different mechanisms of photon absorption, namely the photoelectric effect or the Compton effect. As a consequence,

scanning by a MV-CT results in an almost artefact free image - also in the presence of TTField arrays. A second aspect is the finding, that the allocated CT number of material with a high physical and electron density inversely correlates with the photon energy used for CT-scanning [19]. This leads to shallower ED-HU-conversion curve. The HU-value of the high density arrays is therefore still within the range of the HU table and not at its edge (2854 HU in parts of the arrays, representing a relative ED of 3.9). Based on these considerations we assumed that a MV-CT based dose calculation is more reliable in presence of TTField arrays than a dose calculation based on kV-CTs. The general applicability of MV-CTs for radiotherapy planning was already shown by other groups [20]. This assumption was further substantiated by measurements with a linear accelerator which showed a good accordance of the measurements with the calculations in terms of depth doses as well as with attenuations caused by the TTField arrays.

In principle, the accuracy of a kV-CT based dose calculation can theoretically be improved by extending

the HU-table or replacing the electrodes in the CT dataset by the true electron density – which unfortunately is unknown. However, image artefacts outside the electrodes must also be corrected by the real tissue density and a replacement with one density might be insufficient, too. In addition, finding the correct position of the electrodes can be hampered by the artefacts. In contrast to this approach, MV-CT based dose calculation is free of additional corrections.

Based on these considerations, we investigated the impact of TTField arrays on the MV-CT based calculated dose delivery in two hypothetical cases of glioblastoma.

Comparison of the plans for two exemplary target volumes showed only minor effects on the plan quality. The homogeneity index was not affected when the TTField arrays were added to the setup and the conformity index showed only minor differences. Therefore, radiotherapy with simultaneously applied TTField arrays seems to be possible without negatively affecting the tumor control probability as similar doses are delivered independently from the presence of the arrays. Importantly, to our knowledge, there are currently no data available about possible synergistic effects between TTFields and radiation onto normal tissues.

The doses at deeply seated OARs, such as the chiasm, the optic nerves or the brainstem, were also not increased by more than 0.4 Gy by the presence of the arrays. This is within the range of the inherent dose calculation uncertainties of current treatment planning systems and largely below uncertainties due to positioning errors [21, 22]. However, even a small increase in the D<sub>max</sub> could have detrimental late effects, the dose constraints should be chosen conservatively and met exactly, especially as additional biologic TTField effects on normal tissues are unknown. In summary, based on the criteria of ICRU report 83, the absorbed doses within the PTV as well as

the OAR are affected by the presence of TTField arrays, but the differences are not likely to be of clinical relevance [15]. Or with other words: if an increased rate of adverse events would be observed during concomitant use of TTFields and radiotherapy, with TTField arrays attached during irradiation, then this likely would not be due to a change within the dose delivery but to an additional biologic effects.

Besides only modest effects on the dose-distribution within the depth, a bolus effect caused by the electrodes was shown by us as well as by Bender et al. [14]. Notably, the bolus effect to the skin was not the main focus

of this manuscript and was therefore calculated only for static 0° fields. The overdosing within the skin can still be relevant, but as the positions of the arrays are changed every 3 days, potential side effects, mostly to the skin, can be attenuated. However, since hair loss is present depending on the size and the location of the lesion of the GBM, such overdosing at the skin and hair level might increase the rate of permanent alopecia and should be kept in mind when counselling the patients.

Additionally, daily repositioning can be performed precisely even with the TTField system present during the treatment process, especially when MV-CT can be used for positioning. As the OAR of the CNS are mostly located at the skull base, and as this area is usually not covered by the TTField arrays, sufficient registration of the skull base is also possible with kV-CT or CBCT, too. When soft tissue information is deemed to be important for repositioning, MV-CT based imaging or daily change of the TTField arrays can be performed.

Notably, the biology effects of TTFields and potential additive effects with radiation have only been studied in cell lines of malignant tumors so far and no preclinical evidence about the effect of a concomitant application of TTFields and RT on normal tissue exist. There is a potential risk, that a combination of the two modalities might also increase the risk of side effects. For instance, a reduced fractionation effect could be assumed based on a delayed repair of radiation induced DNA damages, even though this was only shown for malignant cells [8]. This potentially could also lead to an increase in severe late effects, such as radionecrosis. On the other hand, as there is only limited proliferative activity within healthy adult brain tissue and no severe neurotoxicity after TTField-treatment has been reported so far, one could also assume a relatively low risk for an excessive increase in normal tissue side effects by combining these two modalities. Therefore, further preclinical studies on the impact of this modality in normal tissue radiation tolerance as well as treatment within clinical trials are highly recommended before the routine use of concomitant radio-TTField-treatments.

## Conclusion

Electrode arrays of the Optune TTField-system cause streak artefacts on kV-CTs which are impairing trustworthy dose calculations. Our data show that application of the TTField arrays during treatment planning and application of RT does not impact dose calculations, if the dose is calculated based on a MV-CT dataset. Use of MV-CTs for optimizing VMAT plans as well as for recalculation of already optimized VMAT treatment plans reveal only minor effects of TTField arrays on the conformity, homogeneity and median dose as well as the doses at OARs. Noteworthy, an increased skin toxicity

seems to be likely. As the area above the skull base is broadly spared by the TTField arrays and consequently is only slightly effected by artefacts, repositioning can be safely performed also with CBCTs. Based on these findings, irradiation of VMAT plans optimized without the presence of TTField arrays seems to be feasible, yet a possible adverse synergistic interaction of TTFields and radiation onto normal tissues should be considered, too.

## Electrical Field Therapy for Glioblastoma

*Roy E. Strowd, MD reviewing Stupp R et al. JAMA 2017 Dec 19*

Case 1:20-cv-00194-WCG Filed 04/28/20 Page 139 of 1212 Document 11-2 1618

*Adding tumor-treating electrical-field therapy to maintenance temozolomide chemotherapy significantly improved survival in patients with newly diagnosed glioblastoma.*

Tumor-treating fields (TTFields) are a new electrical-field therapy being used to target mitotically active tumor cells, arrest growth, and induce apoptosis in patients with glioblastoma. TTFields are delivered continuously by a transducer array, which is similar to an electroencephalography electrode cap and is worn on a shaved scalp.

A prior planned interim analysis of an industry-funded, multicenter, open-label, randomized, phase III study (EF-14) showed that adding TTFields to maintenance temozolomide chemotherapy significantly prolonged survival in 315 patients with newly diagnosed glioblastoma ([NEJM JW Neurol Feb 2015](#) and [JAMA 2015; 314:2535](#)). Investigators now report final results of the EF-14 study, which includes 695 patients who received TTFields for a median 8.2 months (range, 0–82 months) and were followed for a median of 40 months.

Median progression-free survival (the primary endpoint) was improved with TTFields plus temozolomide versus temozolomide alone (6.7 vs. 4.0 months;  $P < 0.001$ ). Median overall survival (OS) was also improved with the addition of TTFields (20.9 vs. 16.0 months;  $P < 0.001$ ), equating to 18% more patients alive at 1 year, 10% more alive at 3 years, and 8% more alive at 5 years. The benefit of TTFields was observed in all major subgroups. Among the TTFields group, OS was longer for patients who used TTFields for  $\geq 18$  versus  $< 18$  hours per day (22.6 vs. 19.2 months;  $P = 0.009$ ).

## COMMENT

Although this trial lacked a sham intervention, studies without placebo control have changed clinical practice in neuro-oncology, including the registration trial for temozolomide, which was approved without placebo control and is widely used ([N Engl J Med 2005; 352:987](#)). The current study, which incorporated intention-to-treat analysis, central radiology review, and robust molecular characterization, shows a survival advantage and an apparent dose-response. In addition, this therapy is well tolerated by patients, and increased seizure risk has not proven to be an issue. As with new therapies, TTFields continue to be adopted variably in practice. With the publication of these results, clinicians will increasingly care for patients using TTFields.

Dr. Strowd is Assistant Professor of Neurology at Wake Forest School of Medicine in Winston-Salem, NC.

Regarding the randomization, women were randomized by a web-based system (<http://www.randomization.com>) using random blocks of 2, 4, and 6 to receive the pessary or no pessary. Randomization was stratified by cervical length, and separate randomization sequences were created by an independent statistician. However, there was an error in the article. The randomization strata were less than 20 mm and equal or greater than 20 mm to equal or less than 25 mm, not equal or less than 20 mm and greater than 20 mm to equal or less than 25 mm as stated. Using the erroneous cutoff would lead to imbalance between the groups, as Thornton suggested. However, with the correct cutoff, no imbalance was noticed, with 125 women with a cervical length less than 20 mm and 25 women with a cervical length equal or greater than 20 mm to equal or less than 25 mm in each group. The number of women with a cervical length equal or less than 20 mm in Table 1 was correct, as equal or less than 20 mm was the cutoff used for vaginal progesterone therapy, as recommended by guidelines.<sup>2</sup> The article has been corrected online and we apologize for any confusion this may have caused.

Regarding the Kaplan-Meier curves, the numbers of women at risk, reported in Figure 2, were the total number of randomized women minus the number of women who already delivered, regardless of whether they had iatrogenic or spontaneous preterm birth. Therefore, the numbers of women at risk are the same for both curves.

The benefits of the pessary shown in our trial could be explained by the high treatment adherence compared with other trials. There are several ongoing trials evaluating the efficacy of cervical pessary in prevention of preterm birth, and there are plans for an individual patient data meta-analysis that will include our data. The meta-analysis will update prior reviews<sup>3,4</sup> and hopefully will clarify the effect of cervical pessary in prevention of preterm birth.

## Quality of Life in Patients With Glioblastoma Treated With Tumor-Treating Fields

**To the Editor** In a multisite, randomized, phase 3, clinical trial, Dr Stupp and colleagues<sup>1</sup> demonstrated a modest benefit for patients newly diagnosed with glioblastoma treated with tumor-treating fields (TTFields) and temozolomide vs temozolomide alone in progression-free survival (7.1 months for TTFields plus temozolomide vs 4 months for temozolomide alone) and overall survival (20.9 months for TTFields plus temozolomide vs 16 months for temozolomide alone). The authors should justify the current cost of the device (\$20 000 per month) and also discuss the effect on quality of life for both the patients (shaving their head) and family when patients wear the TTFields device 18 hours a day.

Cognitive (Mini-Mental State Examination) and functional (Karnofsky performance score) metrics were included in their analysis, but the use of standardized, health-related quality-of-life scores (such as the European Organisation for Research and Treatment of Cancer quality-of-life questionnaire and its brain-specific module) were not mentioned. Tumor-treating fields plus temozolomide compared with temozolomide alone showed no significant differences in time to a sustained 6-point decline in the Mini-Mental State Examination score.<sup>1</sup> Standardized health-related quality-of-life scores take into account emotional, social, and role functioning.<sup>2</sup> An interim analysis conducted on the first 315 randomized patients did not show significant differences for any of the functional scales on either questionnaire in either treatment group.<sup>2</sup> A larger analysis incorporating 92% of the patients noted that 42% of patients had not completed the questionnaires at the 1-year follow-up.<sup>3</sup> The physical and emotional burden of shaving one's head while wearing the device 18 hours a day (including while sleeping) cannot be underestimated for both patient and family members. In fact, it is the partner, friend, or family member who must change the adhesives, administer scalp care, and adjust the TTFields device when it malfunctions, even in the middle of the night.

Other trials, perhaps with less significant psychiatric implications, may be better suited for patients with newly diagnosed glioblastoma. For example, a phase 3 trial (CeTeg/NOA-09) showed that the combination of lomustine and temozolomide significantly improved median overall survival (37.9 months with lomustine, temozolomide, and radiotherapy vs 31.4 months with temozolomide and radiotherapy alone) in patients with the O<sup>6</sup>-methylguanine-DNA methyltransferase (MGMT) promoter.<sup>4</sup>

In sum, although TTFields plus temozolomide provides an interesting and innovative treatment for newly diagnosed glioblastoma, a better understanding of the effect on patient and family quality of life needs to be assessed, especially to justify TTFields's increased economic and emotional burden.

**In Reply** Our randomized trial demonstrated a consistent improvement in both progression-free and overall survival when TTFields was included in first-line therapy for glioblastoma. The hazard ratio for death was 0.63, translating into an improvement in the 2-year survival rate from 31% to 43%. For comparison, the addition of temozolomide to radiotherapy compared with radiotherapy alone also resulted in a hazard ratio of 0.63, with a 2-year survival rate increasing from 10% to 27%.<sup>1</sup> One may consider the improvements modest, yet these are the most effective proven treatments available.

Cancer treatments, be it surgery, irradiation, chemotherapy, or TTFields, all have their inherent toxicities and inconveniences. The results of the health-related quality-of-life analyses that Dr Kwan and colleagues requested have recently been published in detail.<sup>2</sup> The main adverse effect of TTFields was skin reactions (mostly mild) at the site of electrode placement. We hypothesized that wearing the device could either decrease health-related quality of life through its burden on the patient, including physical impairment or a decreased social or role functioning due to the visibility of the device, or increase it through an improved feeling of well-being related to active participation of both the patient and the caregiver in the fight against the disease. Instead, no statistically significant differences in health-related quality of life between baseline and 12 months were observed between groups, except for itchy skin in the TTFields group. Health-related quality-of-life scores were maintained for a longer period in the TTFields group due to the longer time to tumor progression and survival. Missing longitudinal quality-of-life data are an inherent problem of many studies as is overrepresentation of patients with favorable prognostic factors. However, our mixed-model analyses, accounting for missing data, confirmed the results found in the mean change from baseline analyses.

Kwan and colleagues point out that there may be other treatments that could confer a benefit in outcome. We embrace any future advances made in the treatment of patients with malignant glioma. The TTFields treatment has no overlapping toxicities and thus could be combined with any other

promising therapy; TTFields treatment is an important step toward improvement in survival, but further research is needed to ultimately cure patients with glioblastoma.

## The National Resident Matching Program and Competition for Employment

**To the Editor** Dr Curtin and Ms Signer<sup>1</sup> advocated for the policies of the National Resident Matching Program (NRMP) to maintain “a fair, efficient, and reliable matching process.” However, we believe this article minimizes the inherent inequity of the NRMP binding match commitment, which requires medical students to enter the Match contractually obligated to an employment agreement they have never seen. Matched applicants are then not allowed any negotiation of the employment agreement that they were bound to sign. Rigorous enforcement of these contracts are justified by Curtin and Signer to ensure the “integrity” of the process, which is the only means of securing residency positions in the United States.

The contractual obligation of resident physicians to the NRMP fundamentally violates antitrust laws by undermining competition in recruitment and hiring, thereby lessening employment choice and compensation. In the face of a court challenge to the NRMP, the process has been protected from legal scrutiny by Congress. This was accomplished through an exemption of the NRMP in an amendment to the unrelated Pension Fund Equity Act of 2004. The amendment, which had not undergone hearings before appropriate committees, retroactively and permanently exempted graduate medical education programs from antitrust law.

We agree that the NRMP is efficient and effective; in fact, the 2012 Nobel Prize in Economics was awarded for the algorithm on which the NRMP is based.<sup>2</sup> However, the Congressional exemption of the NRMP from antitrust laws and the secretive means by which it was enacted were not proper. The amendment to the Pension Fund Equity Act of 2004 was not procompetitive, as it prevents fair negotiations at the heart of all employment agreements.<sup>3</sup>

## Development of a Method for Improving the Electric Field Distribution in Patients Undergoing Tumor-Treating Fields Therapy

(Received 30 April 2018, in final form 9 July 2018)

Tumor-treating fields therapy involves placing pads onto the patient's skin to create a low-intensity (1 - 3 V/cm), intermediate frequency (100 - 300 kHz), alternating electric field to treat cancerous tumors. This new treatment modality has been approved by the Food and Drug Administration in the USA to treat patients with both newly diagnosed and recurrent glioblastoma. To deliver the prescribed electric field intensity to the tumor while minimizing exposure of organs at risk, we developed an optimization method for the electric field distribution in the body and compared the electric field distribution in the body before and after application of this optimization algorithm. To determine the electric field distribution in the body before optimization, we applied the same electric potential to all pairs of electric pads located on opposite sides of models. We subsequently adjusted the intensity of the electric field to each pair of pads to optimize the electric field distribution in the body, resulting in the prescribed electric field intensity to the tumor while minimizing electric fields at organs at risk. A comparison of the electric field distribution within the body before and after optimization showed that application of the optimization algorithm delivered a therapeutically effective electric field to the tumor while minimizing the average and the maximum field strength applied to organs at risk. Use of this optimization algorithm when planning tumor-treating fields therapy should maintain or increase the intensity of the electric field applied to the tumor while minimizing the intensity of the electric field applied to organs at risk. This would enhance the effectiveness of tumor-treating fields therapy while reducing dangerous side effects.

### I. INTRODUCTION

Tumor-treating fields (TTFields) therapy is a novel antimitotic cancer treatment modality that disrupts cancer cell replication by applying alternating electric fields of low intensity (1 - 3 V/cm) and intermediate frequency (100 - 300 kHz) [1,2]. Because its efficacy in treating patients with recurrent glioblastoma (GBM) was comparable to that of chemotherapy, but with fewer side effects, TTFields therapy was approved by the U.S. Food and Drug Administration (FDA) in 2011 to treat patients with recurrent GBM. TTFields therapy in combination with chemotherapy was shown to enhance survival compared with chemotherapy alone in patients with newly diagnosed GBM, resulting in its approval by the FDA in 2015 for this indication [3-6]. At present, only six

years after its initial approval by the U.S. FDA, TTFields therapy is being performed to treat GBM in about 950 treatment centers worldwide. Moreover, clinical trials have reported that TTFields therapy is 1.5 - 2.5 times more effective than conventional treatments in patients with lung, pancreatic and ovarian cancer, and it is being evaluated in other types of cancer [7-12].

Efforts are also underway to maximize the therapeutic effects of TTFields therapy. A previous study showed that the force exerted on a microscopic polarizable organelle in the cell is proportional to the square of the electric field, *i.e.*, the electric field intensity [13]. As a result, increases in the electric field intensity have been found to result in greater blockage of cancer cell division and induction of cell death in various cancer cell lines [13-16]. Specific frequency ranges have shown maximum effectiveness at blocking cancer cell division, even at the same electric field intensity [2, 13, 15]. Electric fields of about 200 kHz have shown the maximum effect

Fig. 1. (Color online) Simple Model Structure.

in treating patients with GBM, and the TTFields treatment planning system, NovoTAL software, determines the size and the position of the tumor relative to each patient's individual anatomy and selects the position of the electric pads to maximize the field strength at the tumor during treatment [17–19].

Although TTFields treatment is a promising modality to treat patients with various types of cancers, it has the potential for long-term side effects. It is, therefore, important to study methods that increase the intensity of electric fields applied to tumors, thereby enhancing its therapeutic effects, while minimizing exposure of organs at risk (OARs). Few studies, however, have assessed methods for optimizing the intensities of electric field [20,21]. Optimization algorithms that control the amount of radiation administered are frequently used for patients undergoing conventional radiation therapy [22–24]. These algorithms are based on determinations of the prescribed dose to be applied to the tumor and the allowable dose to OARs that does not cause side effects. This method can more easily control radiation dose to the body than methods in which several conditions (*e.g.*, the amount, direction, and intensity of radiation) are repeatedly changed, requiring re-calculation of radiation doses delivered to the body [25–27].

Similar to planning methods for radiotherapy, we used an optimization algorithm to optimize the electric field distribution in the body, allowing the application of electric fields with the prescribed intensities to tumors while minimizing the intensities of electric fields at OARs. The distributions of the electric fields in the body were compared using this method and existing treatment approaches that do not use optimization algorithms.

## II. EXPERIMENTS

### 1. Design of model

This research was performed using simple self-made models and models based on actual patients' computed tomography (CT) dicom files. The simple model consisted of an 8000-cm<sup>3</sup> cube containing three ovals, each 50.1 cm<sup>3</sup> in volume but at different positions, as well as one 112.5 cm<sup>3</sup> sphere; these represented OARs 1, 2, and 3 and the tumor, respectively (Fig. 1). Three types of

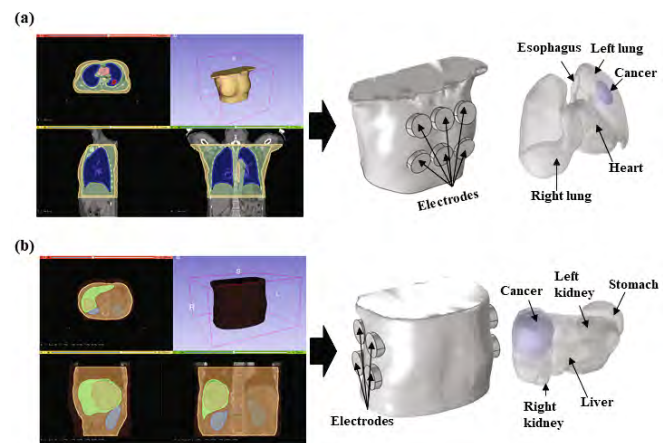

Fig. 2. (Color online) Interior and exterior of the patient model created based on CT data for patients with (a) lung and (b) liver cancer.

models were constructed, differing only in the position of the tumor, which was at the top (Fig. 1(a)), center (Fig. 1(b)), or bottom (Fig. 1(c)) of the cube. The area of each electrode that transmit the electric field to the model was 28.3 cm<sup>2</sup>. Four electrodes are attached to each of the two opposite sides of the cube, with a 2-cm gap between electrodes.

Patient models were based on the CT dicom files of actual patients with lung and liver cancer. In the lung cancer model, OARs, such as the lungs, esophagus, and heart, were segmented based on CT images, and the tumor was drawn on the CT images. In the liver cancer model, OARs, such as the stomach and kidneys, as well as the tumors, were segmented based on CT images. Volume meshes were made via simpleware software (Synopsis, USA) and were transferred to COMSOL Multiphysics software (COMSOL, USA). The lung cancer model included six electrodes, of around 28.5 cm<sup>2</sup>, placed in the area of each of the two opposite skin surfaces whereas the liver cancer model included four electrodes, of around 30.6 cm<sup>2</sup>, in the area of each of the two opposite skin surfaces (Fig. 2).

### 2. Computation of electric fields

The electric fields formed within the models were calculated using the COMSOL AC/DC module, which performs a finite-element analysis of Maxwell's equations. In the simple models, the conductivity of all organs was set at 0.1 S/m, and the permittivity was set at 1000. In the patient models, the conductivity and the permittivity values at 200 kHz were set to values appropriate for each organ from the literature [20,28,29]. Electrodes on the two opposing sides were selected one by one so that all the electrodes on one side could be matched with those on the other side one by one. To calculate the electric

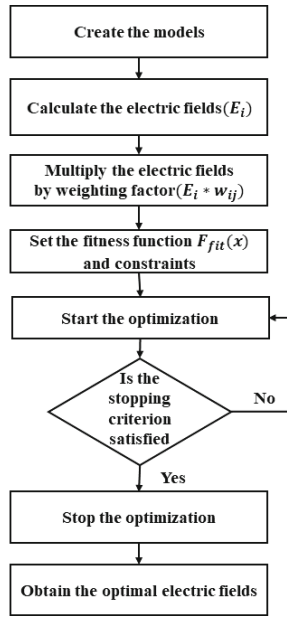

Fig. 3. Process for calculating the optimal electric field distribution through the optimization algorithm.

field, we set the alternating current (AC) voltage of one electrode was to 10–100 V<sub>pp</sub>, 200 kHz and the corresponding electrode at ground. That is, 16 ( $E_1 \sim E_{16}$ ) and 36 ( $E_1 \sim E_{36}$ ) electric field distributions were obtained for models with four and six electrodes on each side, respectively. These electric field distribution values ( $E_i$ ) were each multiplied by weighting factors ( $w_i$ ), and the final distribution ( $E_{\text{final}}$ ) was calculated by the combination of these distribution values, as in Eq. (1).

$$E_{\text{final}}(w_{ij}) = \frac{\sum_{i=1}^n w_{ij} * E_i}{\text{Number of electrodes used}}. \quad (1)$$

### 3. Optimization method

This research used a genetic algorithm (GA), a global optimization algorithm technique based on Darwin's concept of survival of the fittest [30,31]. A randomly created initial population is subjected to three processes (selection, crossover, and mutation) based on the resulting values of a calculated fitness function, to create a population that is more evolved than the initial population. The genetic processes are performed again based on this population's resulting values to create another population, and the process is repeated. When set conditions are met or a better fitness function cannot be obtained, the algorithm is considered to have found the optimal condition (Fig. 3) [31–33].

Equation (2) was set as the fitness function, and optimization was performed to adjust the weighting factors to obtain the minimum fitness function value ( $F_{\text{fit}}$ ). If  $E_{\text{ave1}}$ ,  $E_{\text{ave2}}$ , and  $E_{\text{ave3}}$  are the mean electric field values

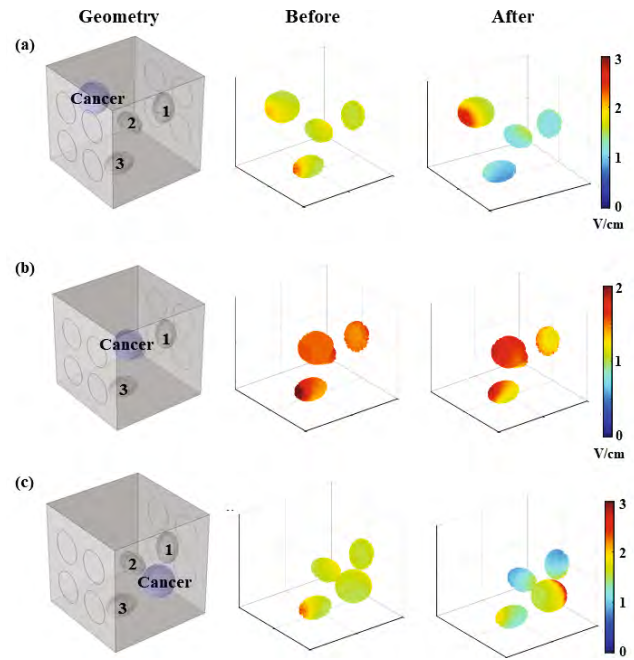

Fig. 4. (Color online) Interior electric-field distributions before and after application of the optimization algorithm for tumors located at the (a)top, (b)center, and (c)bottom of the cube.

transmitted to the OARs, and  $Std_{\text{cancer}}$  is the standard deviation of the electric field intensity transmitted to the tumor, then

$$F_{\text{fit}}(w_{ij}) = E_{\text{ave1}}(w_{ij}) + E_{\text{ave2}}(w_{ij}) + E_{\text{ave3}}(w_{ij}) + Std_{\text{cancer}}(w_{ij}). \quad (2)$$

Constraints were designed to deliver an electric field strength  $\geq 1.5$  V/cm to the tumor and less than the maximum field strength to the OARs when the same electric potential was applied to all electrodes.

### 4. Evaluation method

To evaluate the treatment planning method using the optimization algorithm, we determined the electric field distribution in the body resulting from the application of the same electric potential to all the electrodes on opposite sides. These findings were normalized to allow transmission of an electric field  $> 1.5$  V/cm to the entire volume of the tumor.

The two methods were evaluated by constructing a 3-D map representing the electric field intensity transmitted to the tumor and the OARs (Figs. 4 and 6) and by constructing a graph in which the horizontal axis represent the electric field intensity and the vertical axis represent the percentage of the total volume of a given tissue in which the magnitude of the electric field exceeded that

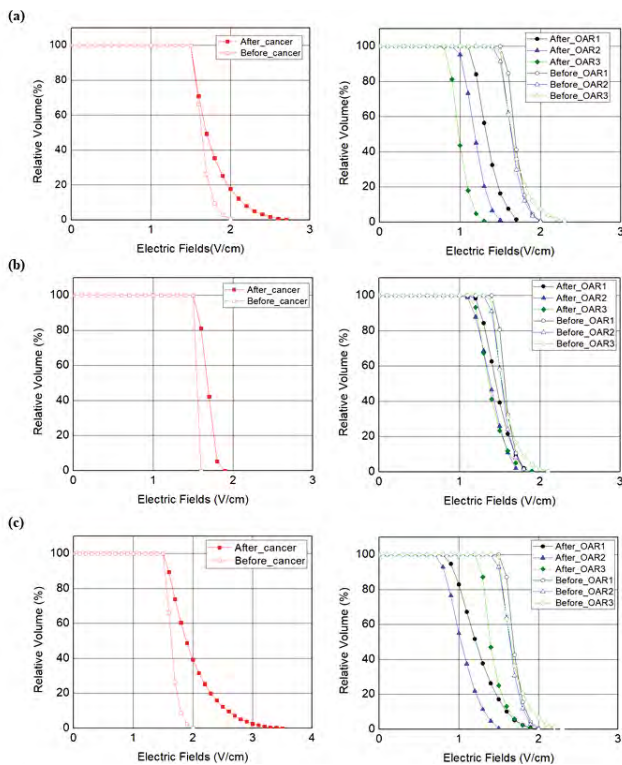

Fig. 5. (Color online) Percentage of the total volume of a given tissue in which the magnitude of the electric field exceeded that along the horizontal axis before and after application of the optimization algorithm for tumors located at the (a) top, (b) center, and (c) bottom of the cube.

in the horizontal axis in V/cm (Figs. 5 and 7), the maximum electric field intensity of the specific organ ( $E_{\max}$ ), the average electric field intensity of the specific organ ( $E_{\text{ave}}$ ), and the values ( $V_{30}$ ,  $V_{60}$ ,  $V_{90}$ ) of the relative volume which had 30% (= 0.45 V/cm), 60% (= 0.90 V/cm), or 90% (= 1.35 V/cm) of 1.5 V/cm transmitted. These factors are those used for evaluating radiation treatment plans [34,35].

### III. RESULTS AND DISCUSSION

#### 1. Simple models

Figure 4 shows 3-D graphs of the internal electric field distributions with (optimization method) and without (existing method) the optimization algorithm, enabling a qualitative determination of the electric field intensity transmitted to each internal organ. In all three models, there were more areas of application of  $\geq 2$  V/cm electric field intensity to the tumor than in the existing method, along with many areas of application of  $\leq 1$  V/cm electric-field intensity at the OARs. A comparison of the two methods in Fig. 4(a) showed that the

Fig. 6. (Color online) Distributions of internal electric fields in a liver cancer model before and after application of the optimization algorithm.

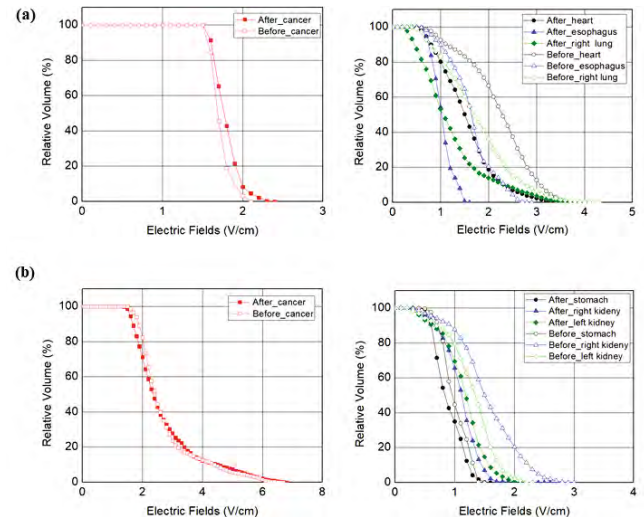

Fig. 7. (Color online) Percentage of the total volume of a given tissue in which the magnitude of the electric field exceeded that along the horizontal axis before and after application of the optimization algorithm in the (a) lung and (b) liver cancer models.

optimization method increased the area of the tumor exposed to  $\geq 2$  V/cm by more than half and reduced the intensity to most OARs from 1 - 1.5 V/cm to  $< 1$  V/cm. In Fig. 4(b), the optimization method increased the intensity to most of the tumor to  $\geq 2$  V/cm and altered the intensity to most OARs from 1.5 - 2 V/cm to around 1 V/cm. In Fig. 4(c), the optimization method increased the area of the tumor exposed to 2 V/cm by around half and reduced exposure of about half of the OARs from 1.5 - 2 V/cm to  $< 1$  V/cm. Also, regardless of whether the existing method or the optimization method was used, the electric fields were greater in some parts of the tumor than in other parts and were greater for OARs near the surface than for OARs at deeper locations. This was likely due to the greater electric field intensity in areas close to, rather than more removed from, an electrode, thereby increasing exposure of organs near surface electrodes.

The treatment plan was designed so that the entire volume was exposed to an electric field  $\geq 1.5$  V/cm (Fig. 5). The maximum electric-field intensity transmitted to the tumor was larger after than before using the optimization algorithm (2.77 V/cm vs. 2.40 V/cm, respectively,

in Fig. 5(a); 1.88 V/cm vs. 1.55 V/cm, respectively, in Fig. 5(b); and 3.54 V/cm vs. 2.05 V/cm, respectively, in Fig. 5(c)). The optimization method resulted in the transmission of 0.33 - 1.49 V/cm greater intensity. These findings confirmed that the optimization algorithm made possible the application of a greater electric field to the tumor than the existing method.

In assessing OAR graphs (Fig. 5), we found that all the graphs for the optimization method were positioned to the left ( $y$ -axis) of the graphs for the existing method, with the optimization method having a similar or lower maximum electric-field intensity. Quantitative analyses also showed that the maximum electric-field intensity was equal or lower using the optimization than the existing method in all three organs at risk in all three models (*i.e.* nine conditions), with differences of 0.00 - 1.06 V/cm (Table 1). The average electric-field intensity was also lower in all nine conditions, with differences of 0.11 - 0.69 V/cm. Comparing the electric-field intensity doses in sections showed that the relative volumes of OARs exposed to 0.45 V/cm ( $V_{30}$ ) were 100%. Compared with the existing method, use of the optimization method reduced the volume exposed to 0.90 V/cm ( $V_{60}$ ) by 5% - 23% in three of the nine conditions and reduced the volume exposed to 1.35 V/cm ( $V_{90}$ ) by 26% - 100% under all nine conditions. That is, the higher the electric field strength is the smaller the volume of normal tissue exposed.

Figure 6 shows the 3-D electric field distribution when an electric field is applied to a CT image-based liver cancer patient model using the existing treatment method

Abbreviations: BO, before application of the optimization algorithm; AO, after application of the optimization algorithm.

and the optimization algorithm to create treatment plans. The differences in the electric-field intensity were not as obvious as in the simple model, although the use of the optimization algorithm increased the volume of the tumor exposed to 3 V/cm slightly, and reduced the volume of the right kidney exposed to 1 - 2 V/cm, with these areas being exposed to electric-field intensity < 1 V/cm. Use of the optimization algorithm also increased the volume of the stomach exposed to < 0.5 V/cm.

Although the overall shapes of the tumor graphs were similar for the existing and the optimization methods (Fig. 7), the maximum electric-field intensities transmitted to the tumor using these two methods were 2.09 V/cm and 2.35 V/cm, respectively, for the lung cancer model (Table 2(a)) and 6.62 V/cm and 6.72 V/cm, respectively, for the liver cancer model (Table 2(b)). The greater maximum electric-field intensity in the liver model compared to the lung cancer model was likely due to the greater electric-field intensity in areas around the electrode. Because liver tumors are closer to the electrode than lung tumors, the maximum electric-field intensity at the former should be higher.

When we compared each of the OARs, we found that the graph lines of the optimization method were generally to the left ( $y$ -axis) of the graph lines of the existing method (Fig. 7). That is, the electric-field intensity transmitted to each OAR was lower by the optimization method than by the existing method. Quantitative analysis also showed that the maximum electric-field intensity was lower for the optimization than for the existing method for all six OARs in both the lung (Table 2(a)) and the liver (Table 2(b)) cancer models, except for the stomach, with differences ranging from 0.10 - 1.28 V/cm. Although the maximum electric-field intensity for the stomach was greater for the optimization than for the existing method, the difference, 0.08 V/cm, was very small. Similarly, comparisons of average electric-field in-

tensities showed that the intensities transmitted to all six OARs was 0.10 - 0.68 V/cm lower with the optimization method.

Assessment of the relative volume of each organ that experienced each level of electric-field intensity showed that the relative volume that experienced more than 0.45 V/cm ( $V_{30}$ ) was the same for four of the six OARs, but in two of them the optimization method affected a smaller volume. The relative volume exposed to 0.90 V/cm ( $V_{60}$ ) was 7% - 25% smaller with the optimization method than the existing method for all six OARs. Moreover, the relative volume exposed to 1.35 V/cm ( $V_{90}$ ) was 2% - 62% smaller with the optimization method for all six OARs. Thus, similar to the simple model, the volume of normal tissue that experienced high levels of electric-field intensity was lower when the optimization method was used.

When an optimization algorithm is used, large and small electrical potentials are generally applied to the electrode near the tumor and the electrode near the OARs, respectively. Therefore, if optimization is used, local electric field intensities applied to the patient's skin below the electrodes can be relatively large or small based on the locations of the electrodes. However, the averages of the electric field intensity applied to the entire skin stayed the same before and after optimization. Our experimental results showed that average electric fields applied to the skin before and after optimization were 0.82 V/cm (0.59 V/cm) per unit skin area and 0.73 V/cm (0.4 V/cm) per unit skin area for the liver (lung), respectively. Although electrode induced local electric fields applied to patient's skin can be relatively large causing skin side effect, this phenomenon can be avoided if the limit of electric field is applied during optimization.

In addition to intensity modulation of the TTFields, one can adjust the electrode size to optimize the electric field inside body. In general, when a small electrode is used, there are several advantages. First, there will be more electrodes (*i.e.*, variables) that can be manipulated to focus the electric field inside body. Second, small electrode can be easily attached to the skin, which is very important issue in TTF therapy. However, if one uses only small electrodes, the high electric field acquired by optimization can be applied to a very small area just below the specific electrode, which might cause a side effect in the skin. On the other hand, when a large electrode is used, it is an advantage to apply a uniform electric field in the body with relatively small electric field on the skin. But, as mentioned before, it might be difficult for large electrode to be attached to the patient's skin completely. Therefore, the appropriate sizes of electrodes are very important in optimization of electric field using intensity modulation and future study is called to investigate the optimal electrode size and field intensity for the best outcome of tumor treating fields.

## IV. CONCLUSION

This study compared the electric-field distributions in the body produced using an optimization algorithm and an existing treatment method. The optimization method resulted in application of a greater electric-field intensity to the tumor while minimizing the electric field intensity at OARs. Use of this method in actual treatment plans may not only increase the effectiveness of the treatment, but also reduce as yet undetermined side effects of TTFields therapy. In the future, we will study the difference in the electric field distribution due to the different electric susceptibilities of organs and prostheses to improve the effect of TTFields therapy.

# Influence of Treatment With Tumor-Treating Fields on Health-Related Quality of Life of Patients With Newly Diagnosed Glioblastoma

## A Secondary Analysis of a Randomized Clinical Trial

Martin J. B. Taphoorn, MD; Linda Dirven, PhD; Andrew A. Kanner, MD; Gitit Lavy-Shahaf, PhD; Uri Weinberg, MD, PhD; Sophie Taillibert, MD; Steven A. Toms, MD; Jerome Honnorat, MD, PhD; Thomas C. Hottinger, MD, PhD; Yvonne Kew, MD, PhD; Patrick Roth, MD; Rajiv Desai, MD; John L. Villano, MD, PhD; Eilon D. Kirson, MD, PhD; Zvi Ram, MD; Roger Stupp, MD

**IMPORTANCE** Tumor-treating fields (TTFields) therapy improves both progression-free and overall survival in patients with glioblastoma. There is a need to assess the influence of TTFields on patients' health-related quality of life (HRQoL).

**OBJECTIVE** To examine the association of TTFields therapy with progression-free survival and HRQoL among patients with glioblastoma.

**DESIGN, SETTING, AND PARTICIPANTS** This secondary analysis of EF-14, a phase 3 randomized clinical trial, compares TTFields and temozolomide or temozolomide alone in 695 patients with glioblastoma after completion of radiochemotherapy. Patients with glioblastoma were randomized 2:1 to combined treatment with TTFields and temozolomide or temozolomide alone. The study was conducted from July 2009 until November 2014, and patients were followed up through December 2016.

**INTERVENTIONS** Temozolomide, 150 to 200 mg/m<sup>2</sup>/d, was given for 5 days during each 28-day cycle. TTFields were delivered continuously via 4 transducer arrays placed on the shaved scalp of patients and were connected to a portable medical device.

**MAIN OUTCOMES AND MEASURES** Primary study end point was progression-free survival; HRQoL was a predefined secondary end point, measured with questionnaires at baseline and every 3 months thereafter. Mean changes from baseline scores were evaluated, as well as scores over time. Deterioration-free survival and time to deterioration were assessed for each of 9 preselected scales and items.

**RESULTS** Of the 695 patients in the study, 639 (91.9%) completed the baseline HRQoL questionnaire. Of these patients, 437 (68.4%) were men; mean (SD) age, 54.8 (11.5) years. Health-related quality of life did not differ significantly between treatment arms except for itchy skin. Deterioration-free survival was significantly longer with TTFields for global health (4.8 vs 3.3 months;  $P < .01$ ); physical (5.1 vs 3.7 months;  $P < .01$ ) and emotional functioning (5.3 vs 3.9 months;  $P < .01$ ); pain (5.6 vs 3.6 months;  $P < .01$ ); and leg weakness (5.6 vs 3.9 months;  $P < .01$ ), likely related to improved progression-free survival. Time to deterioration, reflecting the influence of treatment, did not differ significantly except for itchy skin (TTFields worse; 8.2 vs 14.4 months;  $P < .001$ ) and pain (TTFields improved; 13.4 vs 12.1 months;  $P < .01$ ). Role, social, and physical functioning were not affected by TTFields.

**CONCLUSIONS AND RELEVANCE** The addition of TTFields to standard treatment with temozolomide for patients with glioblastoma results in improved survival without a negative influence on HRQoL except for more itchy skin, an expected consequence from the transducer arrays.

Glioblastoma has a poor prognosis,<sup>1,2</sup> and, as tumors grow, patients often experience a progressive decline in neurologic function and health-related quality of life (HRQoL).<sup>3-7</sup> The current standard of care is not curative but results in prolongation of life. However, extension of survival is meaningful only if patients' functioning and well-being can be retained or improved.<sup>8-11</sup> Therefore, it is important to determine the net clinical benefit of each new treatment or treatment modality introduced; possible benefits of a new treatment, in terms of prolonged survival, have to be carefully weighed against potential negative effects of the treatment on the patients' quality of life.

The current standard of care for patients with newly diagnosed glioblastoma comprises surgical resection to the extent safely feasible followed by radiotherapy with concomitant and maintenance chemotherapy with temozolomide.<sup>12</sup> Tumor-treating fields (TTFields) (Optune; Novocure Ltd) is an antimitotic physical treatment modality<sup>13,14</sup> delivered by a home use medical device with wired transducer arrays placed on the patients' scalp. When added to standard maintenance temozolomide chemotherapy, TTFields has been demonstrated to improve both progression-free survival and overall survival in a randomized clinical trial (NCT00916409).<sup>15</sup>

Treatment with TTFields involves the patient carrying a mobile electrical device for more than 18 hours per day and having 4 arrays of transducers continuously fixed to the shaved scalp. Concerns regarding the influence of wearing the device on patients' HRQoL have therefore been raised.<sup>16,17</sup> The incidence of adverse events was not increased by the addition of TTFields to temozolomide therapy except for an expected mild to moderate skin irritation beneath the electrodes in 52% of patients (severe in 2%). Herein, we report on the influence of treatment with TTFields on the patients' HRQoL, which was a predefined secondary objective of the randomized clinical trial. The present study was conducted from July 2009 until November 2014, and patients were followed up through December 2016.

## Methods

### Study Population

Patients eligible for this study were aged 18 years or older, had newly diagnosed and histologically confirmed supratentorial glioblastoma (World Health Organization grade IV astrocytoma), were progression free after undergoing maximal safe debulking surgery or biopsy, and had completed standard radiotherapy with concomitant temozolomide. Patients were required to have a Karnofsky Performance Status score of at least 70 at the time of enrollment, corresponding to at least being able to perform self-care. Further details on the study population are available elsewhere.<sup>15</sup> All patients provided written informed consent, and the study was approved by the institutional review boards or ethics committees of all participating centers and the relevant competent authorities (eAppendix 1 in Supplement 1); the participants did not receive financial compensation.

### Key Points

**Question** What is the influence of adding tumor-treating fields to the standard treatment on health-related quality of life in patients with glioblastoma?

**Findings** In this secondary analysis of the EF-14 randomized clinical trial, the addition of tumor-treating fields did not negatively influence health-related quality of life except for itchy skin, an expected consequence from the transducer arrays.

**Meaning** Tumor-treating field therapy has previously been shown to prolong both progression-free and overall survival. When considering the net clinical benefit, improved survival without a negative influence on health-related quality of life supports the addition of tumor-treating fields to standard treatment in patients with glioblastoma.

### Study Design and Treatment

This prospective, multicenter, open-label, randomized clinical phase 3 trial recruited 695 patients at 90 medical centers in North America, Europe, the Republic of Korea, and Israel. The trial protocol is available in Supplement 2. The trial was designed to test the efficacy of TTFields in combination with the best standard of care in the treatment of newly diagnosed glioblastoma (ie, radiotherapy with concomitant and adjuvant temozolomide). The primary end point was progression-free survival, with overall survival as a powered secondary end point. Health-related quality of life was a secondary end point. Patients who were progression free after completion of radiochemotherapy were randomized within 4 to 7 weeks at a ratio of 2:1 to receive standard maintenance temozolomide chemotherapy (150-200 mg/m<sup>2</sup> for 5 days every 28 days for 6 cycles) with or without the addition of TTFields. If tolerated well, TTField therapy was to be continued until the second progression or up to 2 years.

Patients in the TTFields plus temozolomide group received continuous TTFields combined with maintenance temozolomide. TTFields were delivered through a portable device in an outpatient setting. Patients receiving TTFields had 4 transducer arrays with 9 insulated electrodes each placed on the shaved scalp and connected to a portable device set to generate 200-kHz electric fields within the brain. Although uninterrupted treatment was recommended, the patient could take short breaks if needed; patients were advised to continue treatment for at least 18 hours a day. More details on the study design and treatment are published elsewhere.<sup>15</sup>

### HRQoL Assessment

The evaluation of HRQoL was performed using the validated European Organisation for Research and Treatment of Cancer (EORTC) quality-of-life questionnaire (QLQ-C30) and brain module (QLQ-BN20).<sup>18-20</sup> Questionnaires were completed on paper at baseline (prior to randomization) and subsequently every 3 months for up to 12 months. Nine scales and items were preselected as important based on relevance for patients with glioblastoma and hypothesized effects of the TTFields delivery device on patients' HRQoL: global health status; physical, cognitive, role, social, and emotional functioning; itchy skin;

pain; and weakness of legs. We hypothesized that any burden of carrying the device (on physical functioning and itchy skin) or detriment to social and role functioning due to the visibility of the therapy may be balanced by patients' feeling of well-being (global health status and emotional functioning) related to active participation of both the patient and the caregiver in the fight against cancer and increasing patient empowerment. Moreover, we hypothesized that treatment with TTFields would not have an influence on cognitive functioning, pain, and weakness of legs.

### Statistical Analysis

#### Calculation of HRQoL Scores

The items on both questionnaires were scaled and scored using the recommended EORTC procedures.<sup>21</sup> Raw scores were transformed to a linear scale ranging from 0 to 100, with a higher score representing a higher level of functioning or higher level of symptoms. The results of this study are presented in accordance with guidelines for reporting HRQoL in cancer clinical trials and methods.<sup>22-24</sup> Differences of at least 10 points (on a 0-100 scale) were classified as the minimum clinically meaningful change in any HRQoL scale/item.<sup>24</sup>

#### Descriptive Statistics

Descriptive statistics were used to report HRQoL scores as well as the sociodemographic and clinical variables for the population of patients who completed at least 1 HRQoL scale at baseline separately for both treatment groups. Means and SDs or medians and ranges were calculated for continuous variables depending on the distribution of the variable. Frequencies and percentages were calculated for nominal variables. Differences between arms were tested using a 2-sided  $\chi^2$  test or an independent 2-tailed, unpaired *t* test or Mann-Whitney test at an  $\alpha$  value of .05 for each variable.

Adherence to HRQoL assessments was calculated as the number of forms received divided by the number of forms expected at every assessment. Patients who completed the assessments at the time of progression were included in this analysis.

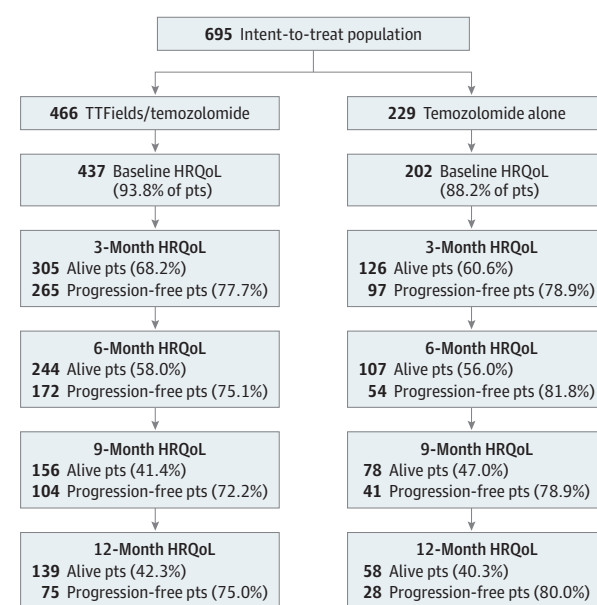

#### HRQoL Scores Over Time

Mean HRQoL scores over time were calculated as well as the mean changes from baseline. A stable HRQoL score was defined as a change of less than 10 points, and a change of 10 or more points indicated a deterioration or improvement depending on the scale or item. Mean change from baseline was plotted to evaluate the longitudinal course of patients' experience of disease and treatment, and a linear mixed-model repeated-measures analysis was used to estimate the treatment effect over time. A sensitivity analysis of complete cases using multiple imputations with a predictive mean matching regression model was used to check the robustness of the treatment effect over time. An additional sensitivity analysis used a repeated-measures model that assumes there is random variation among participants that is related to the time of dropout.

#### Stable or Improved HRQoL During the Progression-Free Period

The percentage of patients with stable (<10-point change) or improved ( $\geq$ 10-point change) HRQoL during the progression-

Figure 1. Consort Diagram

Data are the number and percentage of patients in the categories (baseline, alive, and progression-free) who completed the health-related quality-of-life (HRQoL) questionnaire at the indicated times. pts indicates patients; TTFields, tumor-treating fields.

free period, thus excluding the HRQoL assessment at progression, was determined separately for both treatment arms. This calculation was based on the total number of patients with a valid baseline HRQoL assessment and at least 1 additional follow-up assessment. Moreover, the area under the curve of stable or improved HRQoL for the entire duration of stability or improvement was determined, and differences between arms were assessed with the trapezoidal method (eAppendix 2 in Supplement 1).

#### Deterioration-Free Survival and Time to Deterioration

Deterioration-free survival was defined as the time to a greater than 10-point deterioration in scores from baseline without a subsequent 10-point or more improvement in scores compared with baseline, progressive disease, or death in the absence of a previous definitive deterioration before the next assessment. Disease progression was included as a surrogate measure. Data were censored at the last HRQoL assessment date for patients with a change of less than 10 points, patients who did not progress, or patients who died after 9 weeks since the last assessment. Data for patients with missing baseline scores were not included, and patients missing all postbaseline HRQoL assessments were censored at randomization. Time to deterioration (TTD) was defined similarly to deterioration-free survival, with the exception that progressive disease was excluded as an event (ie, nonmissing HRQoL data beyond progression were included). Kaplan-Meier methodology was used to estimate deterioration-free survival and TTD distributions and median times, and 95% CIs were computed using the Greenwood formula. The difference between treatment arms

SAS, version 9.4 (SAS Institute) was used for all statistical analyses, and comparisons between groups were based on the intent-to-treat principle. *P* values <.05 were considered to be

Figure 2. Changes in Global Health Status and Itchy Skin

Mean changes in points on health-related quality of life scales from baseline in global health status (A) and itchy skin with (B) with tumor-treating fields (TTFields) plus temozolomide compared with temozolomide alone. No change,

between 0 and 10 points; improvement and deterioration, changes of 10 points or more. Error bars indicate SD.

statistically significant. The Hochberg procedure was used to adjust for the multiplicity of treatment comparisons in the pre-selected HRQoL scales analyses.

## Results

### Patients

A total of 695 patients were randomly assigned in a 2:1 ratio to TTFields plus temozolomide ( $n = 466$ ) or temozolomide alone ( $n = 229$ ). A total of 639 (91.9%) patients completed at least 1 HRQoL scale at baseline: 437 (93.8%) of those in the TTFields plus temozolomide arm and 202 (88.2%) patients in temozolomide-alone arm (Figure 1). The baseline demographics of the patients who provided HRQoL data were comparable to those of the intention-to-treat population<sup>15</sup> and were well balanced between treatment arms in this subpopulation (Table 1).

### HRQoL Completion Rates and Baseline Scores

Adherence to HRQoL assessments decreased from 91.9% at baseline to 65.8% (431 of 655 patients alive) at 3 months and dropped to 41.7% (197 of 473 patients alive) at 12 months of follow-up (Figure 1). Mean and median baseline HRQoL scores were comparable between arms for all preselected scales/items (eTable 1 in Supplement 1), as well as the exploratory scales and items. Reference values of HRQoL scores of a healthy general population<sup>25</sup> were available for 7 of 9 predefined scales and items (except itchy skin and weakness of legs). Patients with glioblastoma after completion of radiochemotherapy showed clinically relevant worse functioning or more symptoms compared with the general population on all scales except pain, which was similar.<sup>25</sup>

### Mean Changes in HRQoL From Baseline and the Repeated-Measures Mixed-Effect Model

Mean changes in HRQoL over time for the global health status is presented in Figure 2A and for all 9 predefined HRQoL scales

in the eFigure in Supplement 1. Throughout the 12-month assessment period, mean changes from baseline were stable (<10-point change from baseline) for all 9 predefined HRQoL scales in both treatment arms (eFigure in Supplement 1) with the exception of itchy skin (Figure 2B). For itchy skin, a clinically relevant deterioration (ie, an increase in itchy skin) compared with baseline was seen at the month 3 evaluation in the TTFields plus temozolomide arm (mean [SD] increase, 10.4 [30.1] points vs an improvement of 2.3 [24.4] points in the temozolomide arm). For differences between treatment arms, patients treated with TTFields plus temozolomide had significantly and clinically relevant worse itchy skin at 3, 6, and 9 months than patients treated with temozolomide alone, but not at 12 months (mean [SD] increase of 10.4 [30.1] in the TTFields plus temozolomide arm vs a decrease of 2.3 [24.4] in the temozolomide-alone arm,  $P = .005$ ; increase of 8.1 [31.6] in the TTFields plus temozolomide arm vs a decrease of 4.2 [31.4] in the temozolomide-alone arm,  $P = .008$ ; increase of 5.3 [28.0] in the TTFields plus temozolomide arm vs a decrease of 5.2 [29.6] in the temozolomide-alone arm,  $P = .04$ ; increase of 4.6 [32.8] in the TTFields plus temozolomide arm vs a decrease of 1.9 [36.9] in the temozolomide-alone arm,  $P = .66$ , respectively). For all other scales, there were no statistically significant or clinically relevant differences between treatment arms.

The repeated-measures mixed-effect model supported this finding, with no statistically significant difference between treatment arms in HRQoL scores over time in any predefined scale or item except for itchy skin ( $P < .001$ ), which was worse in the TTFields plus temozolomide arm (eTable 2 in Supplement 1). The sensitivity analyses showed that the results of the linear mixed model were robust.

### Stable or Improved HRQoL During Progression-Free Time

Compared with baseline, more patients in the TTFields plus temozolomide arm compared with the temozolomide-alone arm reported stable or improved scores for global health status (53.5% vs 38.0%, respectively,  $P = .001$ ), physical func-

Median duration (95% CI), mo	6.0 (4.7 to 6.3)	6.7 (5.6 to 9.4)	.37	
Median CFB AUC until last stable/improved status (95% CI)	0 (0 to 0)	0 (−102.2 to 0)	.19	

Abbreviations: AUC, area under the curve; CFB, change from baseline; TTFields, tumor-treating fields.

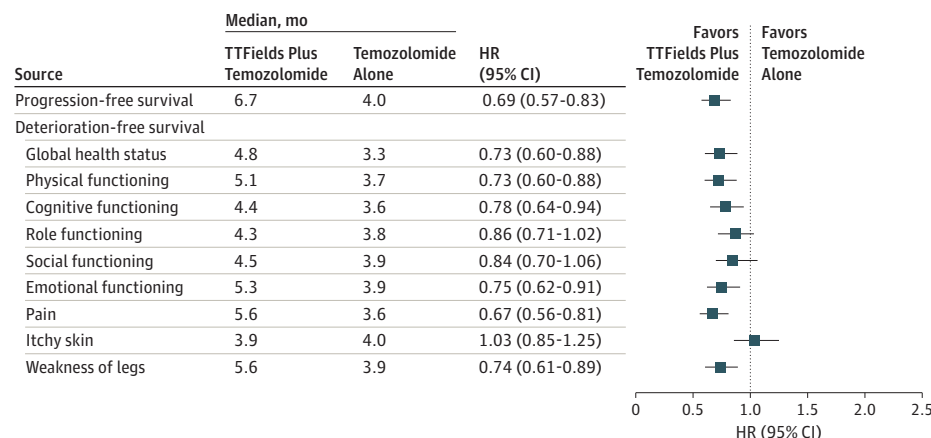

tioning (54.0% vs 37.0%, respectively;  $P = .001$ ), pain (56.8% vs 35.9%, respectively;  $P < .001$ ), and weakness of legs (58.7% vs 42.0%, respectively;  $P = .001$ ) but not in any of the other HRQoL scales and items. However, the duration of stable or improved HRQoL was shorter in the TTFields plus temozolomide arm, although not significantly different from the temo-

zolomide arm for any of the HRQoL scales and items. Overall, with a combination of these measures, the area under the curve analysis showed no significant differences between treatment arms for any of the HRQoL scales and items, indicating a similar HRQoL between treatment arms while patients did not experience tumor progression (Table 2).

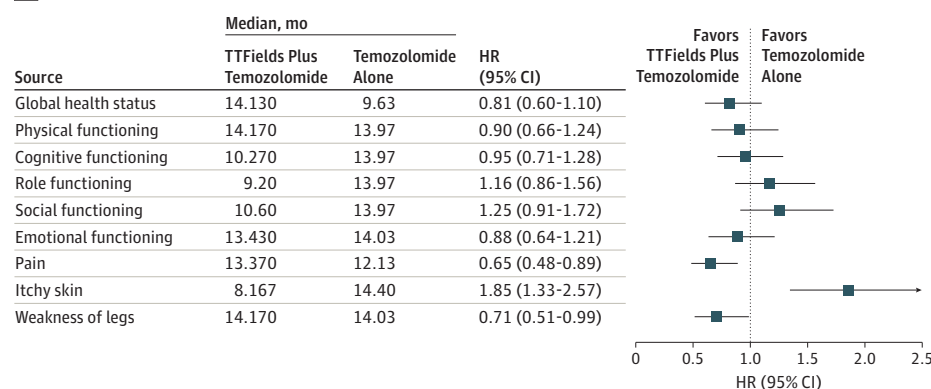

Figure 3. Deterioration-Free Survival and Time to Deterioration

## A Deterioration-free survival

## B Time to deterioration

Deterioration-free survival (A) and time to deterioration (B) for health-related quality-of-life domains in patients who received tumor-treating fields (TTFields) plus temozolomide compared with temozolomide alone. HR indicates hazard ratio.

## Deterioration-Free Survival and TTD

The addition of TTFields to standard temozolomide chemotherapy resulted in statistically significant longer deterioration-free survival in global health status, physical and emotional functioning, pain, and weakness of legs (Figure 3A and eTable 2 in Supplement 1); the significant difference remained after correction for multiple testing. When progression was removed as a deterioration event (TTD), there was no negative influence of TTFields plus temozolomide treatment on the TTD of HRQoL (Figure 3B) except for itchy skin, which was worse in the TTFields plus temozolomide arm (8.2 vs 14.4 months). In contrast, the addition of TTFields to temozolomide resulted in a statistically significant prolongation until deterioration for pain (13.4 vs 12.1 months,  $P < .01$ ). There were no other significant differences in TTD between arms (Figure 3B).

## Discussion

In our detailed analysis of HRQoL during therapy with TTFields in addition to temozolomide, no significant difference was found between the groups in patients' HRQoL over time except for the skin reaction. As expected, itchy skin was reported more frequently in patients treated with TTFields be-

cause of the transducer arrays that have to be placed on the scalp of the patient. Consistently, over half of the patients also reported skin irritation as an adverse event. We had hypothesized that patients treated with TTFields may have better HRQoL in some domains as a result of active participation in the fight against cancer and the frequent interactions between patients and caregivers and device technicians regarding the device. However, on a group level, global health status and emotional functioning were not significantly different between treatment arms. Likewise, our hypotheses that the addition of TTFields would result in worse role and social functioning (due to the visibility of the device) and worse physical functioning were not confirmed. In line with our hypotheses, cognitive functioning, pain, and weakness of legs were not negatively affected by the addition of TTFields to temozolomide treatment. Most relevant for patients, HRQoL was maintained (in 8 of 9 of the predefined scales/items) over time. Combining the results of the survival and HRQoL analyses suggests that the addition of TTFields to adjuvant temozolomide is of value to patients with glioblastoma.

Patients who received TTFields had significantly longer deterioration-free survival compared with those in the temozolomide-alone arm for global health status (4.8 vs 3.3 months;  $P < .01$ ), physical (5.1 vs 3.7 months;  $P < .01$ ) and

emotional functioning (5.3 vs 3.9 months;  $P < .01$ ), pain (5.6 vs 3.6 months;  $P < .01$ ), and weakness of legs (5.6 vs 3.9 months;  $P < .01$ ). For the other scales and items, there was no significant difference in deterioration-free survival between the 2 treatment arms. The prolonged deterioration-free survival for these scales is explained by the extended progression-free survival for patients in the combined TTFields plus temozolomide arm, as progressive disease is included as an event in this analysis. Therefore, TTD analyses, excluding progressive disease as an event, is important to illustrate the influence of a treatment on HRQoL: TTD was not significantly different across any HRQoL scale or item in TTFields-treated patients except for pain and itchy skin, indicating that treatment with TTFields had an influence only on the level of pain and itchy skin. In patients treated with TTFields, TTD was significantly longer for pain (13.4 vs 12.1 months;  $P < .01$ ) and significantly shorter for itchy skin (8.2 vs 14.4 months;  $P < .001$ ). The difference between deterioration-free survival and TTD indicates the importance of disease progression (rather than treatment) as a key event driving HRQoL decline, as suggested by previous studies.<sup>26,27</sup> Moreover, in only 1% of patients, regardless of treatment arm, was a clinically relevant improvement in HRQoL seen after initial deterioration, supporting this observation. Taken together, the results of the deterioration-free survival and TTD analyses support the results of the longitudinal analysis by showing that the addition of TTFields to the standard of care did not adversely affect HRQoL. In fact, the delay in TTD for pain seen in TTFields-treated patients may reflect a delay in the occurrence of tumor-related headaches (although not significant, patients in the TTFields plus temozolomide arm had a longer TTD compared with patients in the temozolomide-alone arm for headaches: hazard ratio, 0.77; 95% CI, 0.54-1.10;  $P = .16$ ). Future studies are needed to better understand this finding, as the median TTD values for pain were longer than the median progression-free survival for both arms.

## Limitations

A common problem in many cancer clinical trials, as in this study, is missing HRQoL data. This absence is especially apparent during the follow-up period, hampering longitudinal data analysis. Patients with better prognostic factors and a good treatment response will be overrepresented at later stages.<sup>28,29</sup> However, our mixed-model analyses, accounting for missing data, confirmed the results found in the mean change from baseline analyses. Another limitation of clinical trials is generalizability of results—patients in clinical trials may not be representative of a general glioblastoma population. Patients in this trial were included only if they successfully completed the combined radiochemotherapy. In addition, it may be that not all patients are prepared to accept wearing the TTFields device. Nevertheless, patients participating in this trial were similar with respect to clinical characteristics to those participating in the EORTC 26981 study<sup>12</sup> comparing radiotherapy alone with radiotherapy plus temozolomide. Lastly, many factors may affect HRQoL, such as age, comorbidity, tumor characteristics, previous antitumor treatment (eg, radiation dose), and supportive treatment. However, it is unlikely that these factors influenced our conclusion, as the objective of this study was to compare HRQoL results between 2 treatment arms in which patients were similar due to randomization.

## Conclusions

Use of TTFields prolongs progression-free and overall survival in patients with glioblastoma. The addition of this novel device-delivered treatment neither negatively affects nor improves functioning and well-being of the patient, including critical HRQoL issues, such as role, social, and physical functioning. Patients reported more itchy skin, which is a direct and expected consequence of the placement of transducer arrays on the patients' scalp. Considering the net clinical benefit, our HRQoL data support the addition of TTFields to standard therapy in patients with glioblastoma.

**Author Contributions:** Drs Taphoorn and Dirven contributed equally to the study. Drs Stupp and Kirson had full access to all data in the study and take responsibility for the integrity of the data and the accuracy of the data analysis.

**Study concept and design:** Taphoorn, Dirven, Villano, Kirson, Ram, Stupp.

**Acquisition, analysis, or interpretation of data:** All authors.

**Drafting of the manuscript:** Taphoorn, Dirven, Lavy-Shahaf, Bruna, Kirson, Stupp.

**Critical revision of the manuscript for important intellectual content:** Taphoorn, Dirven, Kanner, Lavy-Shahaf, Weinberg, Taillibert, Toms, Honnorat, Chen, Sroubek, David, Idhah, Easaw, Kim, Bruna,

Hottinger, Kew, Roth, Desai, Villano, Ram, Stupp. **Statistical analysis:** Taphoorn, Dirven, Lavy-Shahaf, Kirson.

**Administrative, technical, or material support:** Kanner, Lavy-Shahaf, Weinberg, Taillibert, Toms, Chen, David, Kim, Hottinger, Kew, Roth, Villano, Stupp.

**Study supervision:** Bruna, Roth, Desai, Villano, Kirson, Ram, Stupp.

**Conflict of Interest Disclosures:** Dr Taphoorn has performed paid consultancy for Hoffmann-La Roche. Dr Lavy-Shahaf is an employee of and received personal fees from Novocure during the conduct of the study. Drs Weinberg and Kirson are employees of and own minority stock in Novocure. Dr Taillibert received fees from Centre-de-Recherche-en-Neuro-Oncologie for enrolling patients at Salpêtrière University Hospital during the conduct of the study. Dr Idhah received research support from Foundation ARC, IntselChimos, Beta-Innov, and Carthera and travel support from Carthera and Hoffmann-La Roche and served as a paid member of the advisory boards of BMS, Hoffmann-La Roche, and Lettre du Cancérologue. Dr Hottinger received research support from Novocure and served on advisory boards of Servier and BMS (fees paid to the institution). Dr Roth served as a paid member of the advisory boards of Roche and MSD and received personal fees for lectures on behalf of BMS and Novocure. Dr Ram received grants and personal fees from and owns minority stock in Novocure. Dr Stupp received nonfinancial support from Novocure, and his institution received fees from Celgene, Novartis, AbbVie, Merck KGaA (Darmstadt), and MSD-Merck & Co. Dr Stupp's spouse is a full-time employee of Celgene. No other conflicts were reported.

**Funding/Support:** The study was funded by Novocure Ltd.

**Role of the Funder/Sponsor:** Novocure Ltd had a role in the design and conduct of the study; collection, management, and analysis of the data; and decision to submit the manuscript for publication. The study was designed by Drs Stupp and Ram, together with representatives from Novocure, mainly Dr Kirson. The study oversight was supported and monitored by a clinical research organization, which also held the database. Data were collected by the investigators and monitored by the clinical research organization. The statistical analysis plan for the quality of life analyses was developed by Drs Taphoorn, Dirven, Kirson, and Lavy-Shahaf, the sponsor's statistician. Data interpretation was the responsibility of Drs Taphoorn, Dirven, Kirson, and Stupp. The first draft of this manuscript was developed by Drs Taphoorn, Dirven, Kirson, and Stupp. A subsequent mature draft and prefinal version were circulated among all authors who gave additional input, contributed to, and approved the manuscript. The decision to publish the data and its interpretation was made by Drs Stupp and Ram and was supported by all coauthors.

**Meeting Presentation:** This research was presented as a late-breaking oral presentation at the 2017 American Society for Radiation Oncology Annual Meeting; September 24, 2017; San Diego, California.

**Additional Contributions:** We thank the patients and their families for participating in the trial. We

are grateful to all study investigators, nurses, and supporting staff for providing care to the patients and data management.

**Additional Information:** The study oversight was supported and monitored by a clinical research organization that also held the database. The clinical research organization varied among countries and each was paid by Novocure Ltd.

## Abstract

**Background** Tumor treating fields (TTFields) is a non-invasive, antimitotic therapy. In the EF-14 phase 3 trial in newly diagnosed glioblastoma, TTFields plus temozolomide (TTFields/TMZ) improved progression free (PFS) and overall survival (OS) versus TMZ alone. Previous data indicate a  $\geq 75\%$  daily compliance improves outcomes. We analyzed compliance data from TTFields/TMZ patients in the EF-14 study to correlate TTFields compliance with PFS and OS and identify potential lower boundary for compliance with improved clinical outcomes.

**Methods** Compliance was assessed by usage data from the NovoTTF-100A device and calculated as percentage per month of TTFields delivery. TTFields/TMZ patients were segregated into subgroups by percent monthly compliance. A Cox proportional hazard model controlled for sex, extent of resection, *MGMT* methylation status, age, region, and performance status was used to investigate the effect of compliance on PFS and OS.

**Results** A threshold value of 50% compliance with TTFields/TMZ improved PFS (HR 0.70, 95% CI 0.47–1.05) and OS (HR 0.67, 95% CI 0.45–0.99) versus TMZ alone with improved outcome as compliance increased. At compliance  $> 90\%$ , median survival was 24.9 months (28.7 months from diagnosis) and 5-year survival rate was 29.3%. Compliance was independent of gender, extent of resection, *MGMT* methylation status, age, region and performance status (HR 0.78;  $p=0.031$ ; OS at compliance  $\geq 75\%$  vs.  $< 75\%$ ).

**Conclusion** A compliance threshold of 50% with TTFields/TMZ correlated with significantly improved OS and PFS versus TMZ alone. Patients with compliance  $> 90\%$  showed extended median and 5-year survival rates. Increased compliance with TTFields therapy is independently prognostic for improved survival in glioblastoma.

## Introduction

Glioblastoma (GBM) is the most common and aggressive adult brain tumor, accounting for 56% of all gliomas and 15% of all primary brain tumors with an annual incidence in the United States that increases with age—ranging from 0.2 per 100,000 in 0–19 year old population to the highest rate of 15.3 per 100,000 in the 75–84 year old population [1]. Glioblastoma remains incurable with a median survival of only 15 months until recently [2]. The previous standard treatments for newly diagnosed GBM include maximally safe surgical resection followed by radiation therapy (RT) and adjuvant temozolomide (TMZ) chemotherapy [3].

Tumor treating fields (TTFields) are a unique treatment modality [4, 5] for GBM that affects rapidly dividing glioma cells through the action of low-intensity, intermediate

frequency (200 kHz) alternating electric fields [6–9] that act on microtubules and septin fibers of proliferating cancer cells to disrupt mitosis, inducing mitotic cell death, mitotic catastrophe, and cellular stress characterized by autophagy, and endoplasmic reticulum stress [6–13]. TTFields inhibit DNA damage repair by the expression of DNA repair genes in the BRCA1 pathway [14] and impair cellular migration and invasion [15]. TTFields increases cell death when combined with anti-PD1, chemotherapy and radiotherapy [16–19].

The phase 3 EF-11 study of TTFields in recurrent GBM demonstrated comparable efficacy to best physician choice chemotherapy without treatment limiting systemic adverse effects [20]. Post hoc analysis of the EF-11 trial data showed significantly longer median OS with TTFields at compliance rate of  $\geq 75\%$  ( $\geq 18$  h daily) versus those with a  $< 75\%$  compliance rates [21] and high compliance rates of  $> 90\%$  with EF-11 responders [22]. The Patient Registry Dataset (PRiDe) showed significant improvement in median OS at daily compliance rates of  $\geq 75\%$  versus  $< 75\%$  [23]. The phase 3 EF-14 study in newly diagnosed GBM demonstrated that TTFields plus maintenance TMZ therapy significantly improved PFS and OS without decline in health related quality of life (HRQOL) versus TMZ alone [24–26]. The National Comprehensive Cancer Network (NCCN) has recently (2018) recommended TTFields with TMZ as a standard Category 1 treatment option for newly diagnosed GBM [27].

Unlike systemic therapies, TTFields are only active against cancer cells while the transducer arrays are placed on the scalp and the field generator is continuously administering alternating electric fields of a specific intensity (200 KHz) for GBM. There are no peak-trough fluctuations or half-life associated with TTFields. The specificity of TTFields on anti-mitotic activity of rapidly dividing glioma cells, while sparing normal cell division, enables near continuous cancer therapy with minimal systemic adverse effects. Therefore, active compliance with TTFields therapy is a critical parameter for clinical benefit.

The objective of this subgroup analysis of the EF-14 phase III trial data was to analyze compliance data to correlate TTFields compliance with PFS and OS and identify potential lower boundary for compliance rates with improved clinical outcomes.

## Methods

This subgroup analysis is based on TTFields plus TMZ and TMZ alone patient data from the EF-14 study [24]. The EF-14 trial was a randomized, open-label trial, which enrolled 695 newly diagnosed patients with GBM whose tumor was either resected or biopsied and had also

completed concomitant radiation therapy with adjuvant TMZ therapy. Patients were randomized 2:1 to TTFields plus maintenance TMZ chemotherapy ( $n = 466$ ) or temozolomide alone ( $n = 229$ ). Temozolomide was administered to both groups ( $150\text{--}200\text{ mg/m}^2$ ) for 5 days per 28-day cycle (6–12 cycles). The median time from diagnosis to randomization in both groups was 3.8 months [24].

The primary outcome of this subgroup analysis was to assess the percentage of monthly TTFields compliance as an independent predictor of PFS and OS compared with patients in the TMZ alone treatment group. Compliance data are derived from the internal computerized log file of each NovoTTF-100A (Optune®) device. Percent of the total treatment time during which the NovoTTF-100A treated patients actually received treatment was calculated by analyzing the log file of each device and dividing the total device ‘ON’ time by the prescribed number of 1 month treatment courses.

Patient compliance was calculated as the average percentage of each month the system was delivering TTFields. Progression-free survival and OS data from the TTFields plus TMZ treated group were analyzed in subgroups based on monthly compliance levels of  $< 75\%$  or  $\geq 75\%$  and finer monthly compliance bins of 0 to  $\leq 30\%$ , 30% to  $\leq 50\%$ , 50% to  $\leq 60\%$ , 60% to  $\leq 70\%$ , 70% to  $\leq 80\%$ , 80% to  $\leq 90\%$ , 90% to  $\leq 100\%$ .

The PFS and OS survival curves were constructed using the Kaplan–Meier method. Cox proportional hazards model was used to analyze treatment compliance as an independent predictor of survival controlling for treatment group, sex, *MGMT* methylation status, resection status, Karnofsky Performance Status (KPS) and country of residence (United States versus outside the United States). The threshold for significant interactions in the model was specified at an  $\alpha$  of 0.05.

## Results

In the EF-14 study, 466 patients were randomized to the TTFields plus TMZ therapy group and 229 were randomized to the TMZ alone group [24]. The patient disposition is shown in Supplementary Fig. 1. In summary, for the TTFields plus TMZ group—the majority of patients were men (68%) with a median age of 56 years, and a KPS of 90% [24]. The *MGMT* promoter region was unmethylated in 54% and methylated in 36% patients in the TTFields plus TMZ group [24]. Table 1 shows the baseline demographic characteristics of the TTFields plus TMZ group separated into subgroups based on percent compliance. Overall, the separate percent compliance groups were matched in baseline characteristics both with each other and the full data set of the primary study.

**Table 1** Baseline demographics by TTFields percent average daily compliance

% Compliance	0 to ≤30 (n=22)	30 to ≤50 (n=40)	50 to ≤60 (n=42)	60 to ≤70 (n=46)	70 to ≤80 (n=91)	80 to ≤90 (n=166)	90 to ≤100 (n=43)	TMZ alone (n=229)
Median age, years (range)	55.5 (30–70)	57.5 (25–78)	54.5 (22–79)	55.0 (20–83)	56.0 (30–78)	56.0 (28–80)	52.0 (19–68)	57.0 (19–80)
KPS, median (range)	80.0 (70–100)	90.0 (70–100)	90.0 (70–100)	90.0 (60–100)	90.0 (70–100)	90.0 (70–100)	90.0 (70–100)	90.0 (70–100)

MGMT tissue available and tested, n (%)	16 (73)	34 (85)	39 (93)	35 (76)	71 (78)	142 (86)	37 (86)	185 (81)
Methylated	5 (31.3)	14 (41.2)	12 (30.8)	13 (37.1)	24 (33.8)	49 (34.5)	15 (40.5)	77 (41.6)
Unmethyl- ated	10 (62.5)	15 (44.1)	24 (61.5)	20 (57.1)	41 (57.7)	76 (53.5)	17 (45.9)	95 (51.4)
Invalid	1 (6.3)	5 (14.7)	3 (7.7)	2 (5.7)	6 (8.5)	17 (12.0)	5 (13.5)	13 (7.0)

Analysis of the more refined rates of compliance (smaller bin sizes) shows a trend in favor of longer PFS and OS with progressively higher levels of monthly compliance. A threshold value of  $\geq 50\%$  average monthly compliance with TTFields plus TMZ (Fig. 1) was needed to show an extension of PFS (HR 0.70, 95% CI 0.47–1.05) and OS (HR 0.67, 95% CI 0.45–0.99) compared to TMZ alone. Both PFS and OS were extended when compliance was increased beyond 50%, indicating progressively increased gains in PFS and OS as compliance increases.

Patients with TTFields plus TMZ compliance levels of  $> 90\%$  showed maximum survival benefits (Fig. 2), with a

median PFS of 8.2 months for the TTFields plus TMZ group compared to 4.0 months in the TMZ alone group (HR 0.538, 95% CI 0.365–0.794;  $p=0.0047$ ) and an OS of 24.9 months (28.7 months from diagnosis since time from diagnosis to randomization was 3.8) in the TTFields plus TMZ arm compared to 16.0 months in the TMZ alone group respectively (HR 0.522, 95% CI 0.347–0.787;  $p=0.0007$ ). TTFields plus TMZ treated patients with  $> 90\%$  compliance rate had a 5-year survival rate of 29.3% (Fig. 3).

A compliance level of  $\geq 75\%$  monthly duration of treatment with TTFields plus TMZ was an independent predictor of OS, as was methylated *MGMT* status, age and KPS

### Progression-Free Survival

### Overall Survival

**Fig. 1** Forest plots show the effect of treatment compliance with TTFields plus TMZ on PFS and OS. A threshold value of 50% compliance with TTFields plus TMZ was needed to show a significant extension of OS compared to TMZ alone. Both PFS and OS were

extended with treatment compliance levels  $> 50\%$ . A trend in favor of longer PFS and OS was seen with higher rates of treatment compliance

**Fig. 2** Newly diagnosed GBM patients had maximal treatment benefit from TTFields plus TMZ with compliance rates >90% with a median overall survival of 24.9 months (28.7 months from diagnosis)

**Fig. 3** The annual survival rate was highest for newly diagnosed GBM patients with compliance rates >90% with a 29.3% survival rate over 5 years from randomization

(Table 2) regardless of treatment arm (reference values—compliance <75%), sex (male), resection (biopsy), *MGMT* (negative), and region (USA).

## Discussion

In this subgroup analysis of EF-14 study patients receiving TTFields plus TMZ treatment, a threshold value of  $\geq 50\%$  average compliance with TTFields plus TMZ showed an extension of PFS and OS compared to TMZ alone. Further, patients with monthly compliance >90% had maximal survival benefit with a median survival of 24.9 months (28.7 months from diagnosis) and a 5-year survival of 29.3%. This effect was independent of other prognostic factors such as performance status, age, and *MGMT* methylation status.

**Table 2** Cox proportional hazards model for OS in TTFields/TMZ patients

Parameter	Parameter value	Hazard ratio	Two-sided p-value
Treatment arm	Compliance $\geq 75\%$	0.781	0.031
Sex	Female	0.800	0.069
Resection status	Gross total resection	0.789	0.202
	Partial resection	0.777	0.181
MGMT status	Methylated	0.510	<0.001
	Unknown	0.810	0.131
Region	Outside the USA	1.157	0.199
Age		1.021	<0.001
KPS		0.984	0.006

Compliance was an independent predictor of OS in the full 5-year dataset ( $\geq 75\%$  vs. <75%) [24].

Post hoc analysis of the EF-11 trial data demonstrated longer median OS in TTFields treated recurrent GBM patients with a compliance rate of  $\geq 75\%$  compared to those with a <75% compliance rate (7.7 vs. 4.5 months;  $p=0.042$ ) [21]. This early analysis supported a preliminary target level for treatment compliance ( $\geq 75\%$ ) in clinical practice as well as evidence for a trend suggesting that higher levels of survival benefit were associated with increasing compliance [21]. Data from the PRiDe registry—using data from real-world recurrent GBM patients—also demonstrated improved OS with daily compliance rates  $\geq 75\%$  [23]. The results of the EF-14 sub-group analysis further support a threshold compliance rate of  $\geq 75\%$  for a survival benefit when compared to a compliance rate of <75% in newly diagnosed

GBM patients treated with TTFields plus TMZ. This study demonstrates that a minimal compliance threshold of > 50% with TTFields plus TMZ treatment correlated with significantly improved survival outcomes compared to TMZ alone for newly diagnosed GBM. TTFields were administered to GBM patients with recurrent disease as monotherapy in the EF-11 study and as combination therapy with TMZ in newly diagnosed GBM patients in the EF-14 study. The earlier disease stage and combined treatment may account for the survival benefits seen at a lower minimal compliance threshold in this subgroup analysis of the EF-14 study.

A variety of social and clinical factors contribute to patient compliance with TTFields therapy. Though TTFields are non-invasive and the Optune device is designed to preserve patient functioning during daily activities, initiating TTFields therapy requires some lifestyle modifications when compared to RT or systemic therapies. Some patients may be reluctant to comply with the head shaving required with every array change and wearing the arrays on a shaved head may make some patients self-consciousness, calling attention to their condition [28]. Healthcare providers experienced with TTFields therapy can provide patients assistance with incorporating the therapy in their daily life [28].

TTFields, like oral cancer treatment regimens, are administered in the home and outpatient setting and places the burden of compliance on the patient and their caregivers. Patient, healthcare provider, and treatment related factors can contribute to improved adherence or compliance with oral cancer therapy regimens [29]. Patient related factors include physical limitations, psychological, and social issues such as religious or cultural factors and the lack of a support system. The healthcare provider can also negatively influence compliance with therapy through poor communication and relationship with the patient, as well as failing to optimally select appropriate patients for oral cancer therapy regimens [29].

A good home support system is critical when considering TTFields therapy for a GBM patient [28]. A patient should have at least one support person who can assist with the Optune device operation, assist with managing adverse events, scalp maintenance and array placement. Patients with cognitive issues or poor performance status have been suggested to be more likely to be less compliant with TTFields treatment without home support [28]. However, the current study showed compliance to be independent of KPS and age as a predictor of PFS and OS, contradicting this suggestion. Treatment-related factors influencing compliance include complex treatment regimens, concomitant treatments and side effects. TTFields are not associated with systemic side effects and are less likely to affect concomitant systemic therapy.

The most common side effect in clinical trials was skin irritation for patients treated with TTFields [20, 24, 25].

Dermatological adverse events were the most common adverse events associated with TTFields; 52% of TTFields plus TMZ patients in the EF-14 trial reported mild to moderate skin irritation [24]. Skin irritation is due primarily to the nearly continuous contact of the transducer arrays with the patients shaved scalp between array changes. These events include allergic and irritant dermatitis, mechanical lesions, ulcers and skin lesions [30]. However, most of these dermatological AEs can either be prevented with proper shaving techniques, skin care and array relocations, or treated with appropriate topical regimens as required [30]. Effective skin care strategies can maximize compliance with TTFields therapy and maintain patient QoL over the course of treatment.

A limitation of this study is that it is based on a subgroup analysis of the phase 3 EF-14 trial, and inherently subgroup analyses are prone to type I errors limiting the veracity of the results [31]. In this instance, the subgroup analysis was prespecified in the protocol. However, the results of this investigation corroborate the results of similar analyses of prior clinical investigations [21–23].

## Conclusions

In this subset analysis of the EF-14 trial, a compliance threshold of 50% with TTFields plus TMZ treatment correlated with significantly improved outcomes compared to TMZ alone. Higher levels of treatment compliance with TTFields plus TMZ were associated with increased durations of progression free- and overall-survival suggesting a dose response mechanism for TTFields. This effect was independent of other prognostic factors such as performance status, age, and *MGMT* methylation status. Patients with compliance over 90% had a median survival of 24.9 months (28.7 months from diagnosis) and a 3-, 4-, and 5-year survival of 29.3%. This plateau effect on long term survival has been identified in other GBM treatments which have known immunologic mechanisms of action [32, 33]. The importance of compliance with TTFields therapy in real world clinical settings should be strongly conveyed to patients by their treating physicians and other allied healthcare providers.

## Summary

- Glioblastoma is the most common type of primary brain cancer in adults.
- Despite advances in treatment, life expectancy for patients with glioblastoma is typically less than two years.
- Optune is a wearable technology intended for use in addition to standard therapies — surgical resection, radiation therapy, and chemotherapy — in adults with either newly diagnosed or recurrent glioblastoma. It has also been trialled as a single therapy for adult patients with recurrent glioblastoma.
- Optune delivers alternating electric fields, or “tumour-treating fields,” to the brain to disrupt cancer cell division.
- The evidence suggests that some patients with newly diagnosed glioblastoma treated with Optune may live longer, although which patients are most likely to benefit is not yet entirely clear.
- The cost of therapy with the Optune system is about US\$21,000 per patient, per month.

## Background

Glioblastoma is also called glioblastoma multiforme (or GBM), Grade IV glioma, or Grade IV astrocytoma.<sup>1</sup> In adults, glioblastoma is the most common primary brain cancer (a cancer that originates in the brain).<sup>2,3</sup> Glioblastoma is difficult to treat because the cancer cells infiltrate normal brain tissue with tentacle-like extensions that usually cannot be completely removed surgically. Delivery of drug therapies to the tumour is also impeded by the blood-brain barrier (which protects the brain from harmful substances in the blood).<sup>4,5</sup> And because glioblastoma cancer cells are highly heterogeneous (that is, when they divide, the new cells are not genetically identical to the parent cells), new tumour growth can contain cancer cells that are resistant to treatment.<sup>4,5</sup>

With standard treatments, patients with glioblastoma have a median survival of about 15 months from the time they are diagnosed, and only one in four patients is alive at two years.<sup>4,6-11</sup> Glioblastoma typically recurs within about seven months of initial treatment.<sup>6,10</sup>

A wearable device that emits low-intensity, alternating electric fields is a new addition to treatment options for some patients with glioblastoma.

## The Technology

The Optune system (Novocure, St. Helier, Jersey Isle, UK), initially called NovoTTF-100A, was developed at the Technion – Israel Institute of Technology. It uses pre-set, low-intensity (one to three volts) alternating electrical fields at an intermediate frequency of 200 kHz to create “tumour-treating fields” (TTFields). These TTFields penetrate cell walls to disrupt rapid cancer cell division and cause cell death,<sup>12-14</sup> although the mechanism(s) of action are still not fully understood.<sup>15-17</sup> The TTFields treatment should be administered continuously, for at least 18 hours per day.<sup>14</sup>

The components of the Optune system include:

- four adhesive patches, called transducer arrays, that are worn on the patient’s head, with each array containing nine, insulated ceramic disks
- a connector cable
- a portable electric field generator
- four rechargeable battery packs (the system uses one battery at a time, each battery providing four to six hours of power)
- a customized backpack.<sup>18,19</sup>

The Optune system allows the patient to be mobile, using the battery pack and backpack, while receiving treatment, or the system can be plugged into a regular electrical outlet when the patient is seated or asleep.<sup>19</sup> It weighs about 1.3 kg, including the battery.<sup>18,20</sup>

Patients must shave their heads to allow the transducers to properly adhere to their scalp with a thin layer of conductive hydrogel similar to that used for electrocardiogram pads.<sup>19,21</sup> The transducer arrays are attached to adhesive bandages to hold them in place and are positioned in pairs on the head left and right, front and back.<sup>13,14</sup> Each transducer array is plugged into the connector cable, which is in turn plugged into the battery pack.<sup>19</sup> Replacement transducers are provided in sterile packages, and used transducers are returned to Novocure for disposal.<sup>1,19</sup> Ideally, the arrays are worn continuously for three to four days; but after exercise, or in hot or humid weather, more frequent exchanges may be needed.<sup>22</sup> The scalp must be shaved and cleansed before a new set of arrays can be applied.<sup>19,22</sup> Patients can wear a loosely fitting wig, scarf, or hat over the arrays, but the wires will still be visible.<sup>23</sup>

To help physicians identify the optimal placement location for the arrays on the patient’s head, the manufacturer provides the NovoTAL System software. This software uses data from the patient’s MRI scans to guide placement, and it can also be used to make adjustments to placement, as needed, throughout treatment.<sup>6,8</sup>

## Availability

The Optune system does not currently have a Health Canada Medical Devices Active Licence. However, the system has been used at Canadian hospitals in Ontario, Quebec, Manitoba, and Alberta as part of the multinational EF-14 trial.<sup>24</sup>

The US FDA first approved the Optune system in April 2011 for use in patients older than 22 years with recurrent glioblastoma, after standard medical therapies have been used.<sup>25</sup> In 2015, the FDA expanded the licensing to include the treatment of patients with newly diagnosed glioblastoma, after “maximal debulking surgery and completion of radiation therapy together with concomitant standard of care chemotherapy.”<sup>25,26</sup> The Optune system is also commercially available in Europe, Israel, and Japan.<sup>26,27</sup>

## Cost

A 2016 report by the ECRI Institute notes that the cost of TTFields therapy is substantial — approximately US\$21,000 per patient each month.<sup>28</sup> The cost includes the Optune system, a month’s supply of transducer arrays, and 24-hour technical support.<sup>29</sup> The final EF-14 trial analysis showed the median duration of TTFields treatment was just over eight months.<sup>30</sup>

## Who Might Benefit?

Optune is intended for treatment of glioblastoma in the supratentorial (or upper) region of the brain, not for tumours in the cerebellum or brain stem.<sup>26</sup>

Glioblastoma is more common in older people, and is more common in men than in women.<sup>31</sup> Whereas primary glioblastoma most often affects older patients, secondary glioblastoma, which develops more slowly from a lower-grade glioma, usually occurs in younger patients.<sup>31</sup>

Precise numbers of Canadians with glioblastoma are not available, but based on estimates of the incidence of the disease from the US and Europe, approximately 1,200 Canadians may be diagnosed with glioblastoma each year.<sup>5,9,31</sup> The Brain Tumour Foundation of Canada’s Canadian Brain Tumour Registry is collecting information on the incidence and survival rates for all types of brain cancers, and more comprehensive data should be available within the next few years.<sup>32</sup>

## Current Practice

Patient care should be provided by a multidisciplinary team that includes specialists in neurosurgery, radiation oncology, neuropathology, neuro-oncology, and allied health.<sup>31</sup>

Standard treatment and management for glioblastoma include:

- surgical removal of as much of the tumour as possible while avoiding damage to critical areas of the brain, or biopsy only for inoperable tumours
- radiation therapy beginning three to six weeks after surgery and concurrent chemotherapy with oral temozolomide for three to six weeks
- subsequent maintenance temozolomide therapy for six cycles (or up to twelve months).<sup>4,9,11,31,33-35</sup>

Treatment may be modified for elderly or frail patients.<sup>34</sup>

## Methods

These bulletins are not systematic reviews and do not involve a detailed critical appraisal. They are not intended to provide recommendations for or against a particular technology.

## Study Selection

One author screened the literature search results and reviewed the full text of all potentially relevant studies. Studies were considered for inclusion if the intervention included alternating electric fields for glioblastoma. Conference abstracts and grey literature were included when they provided additional information to that available in the published studies.

## Peer Review

A draft bulletin was reviewed by two clinical experts and the manufacturer.

## Literature Search Strategy

A peer-reviewed literature search was conducted using the following bibliographic databases: MEDLINE, Embase, PubMed, and the Cochrane Library (2017, Issue 6). Grey literature was identified by searching relevant sections of the *Grey Matters* checklist (<https://www.cadth.ca/grey-matters>). No methodological filters were applied. The search was limited to English-language documents published between January 1, 2012 and May 30, 2017. Regular alerts updated the search until project completion; only citations retrieved before December 19, 2017 were incorporated into the analysis. Conference abstracts were retrieved through a search of the Embase database limited to the last two years.

Prognosis is affected by the patient's age, Karnofsky Performance Status (which measures functional ability or disability), the amount of tumour that can be surgically removed, and the molecular features of the glioblastoma, such as genetic alterations associated with a better or worse response to temozolomide chemotherapy.<sup>4,31</sup>

Other drug therapies may be used to treat disease recurrence, but evidence that they improve survival is still not conclusive, and they may cause serious adverse events.<sup>31,36,37</sup>

The 2016 US National Comprehensive Cancer Network consensus-based guidelines include "lower-level" evidence recommendations for alternating electric fields therapy as an add-on treatment option to standard therapy for newly diagnosed patients with glioblastoma in the supratentorial region of the brain; and as a treatment option for patients with recurrent glioblastoma.<sup>3</sup>

## The Evidence

Optune has been assessed in several clinical trials over the past decade;<sup>13</sup> the most recent evidence includes two randomized controlled trials (EF-14<sup>30,38</sup> and EF-11<sup>39</sup>) and the PRiDe Patient Registry Dataset.<sup>40</sup>

In the remainder of this section, the trials and the registry study are described first, followed by summaries of the main outcomes: overall survival, progression-free survival, compliance, quality-of-life, and safety. Smaller case series and subgroup analyses are also noted under the relevant outcomes sections.

Some trials included patients newly diagnosed with glioblastoma,<sup>30,38</sup> whereas others included patients at first, second, or later recurrence of cancer.<sup>39</sup> Consequently, the timing and duration of TTFields treatment varied.<sup>6,17</sup> The drug therapies used in the trials also differed; for example, the use of temozolomide alone, or the use of triple therapy that included temozolomide and/or other drugs.<sup>30,38-40</sup> The trials did not use a sham treatment in the control group, as it was considered impractical and inappropriate to place an additional burden on patients and caregivers (for example, shaving the patient's head and placement of the transducer arrays).<sup>16,30,38</sup>

Most publications on Optune — including studies, reviews, and commentaries — received funding from the manufacturer.<sup>6-9,11,13,14,18,19,21,22,30,38-67</sup>

## Study Characteristics

### EF-14

Interim results from the EF-14 trial — the largest, multinational trial of TTFields therapy — were published in 2015,<sup>38</sup> and the

final study results were published in December 2017.<sup>30</sup> The trial involved 695 patients at 83 centres. Patients were all newly diagnosed with glioblastoma and had all received standard treatment: debulking surgery (to reduce the size of the tumour), where feasible; radiation therapy; and chemotherapy. Participants were randomized at a ratio of 2 to 1 to receive maintenance therapy with either TTFields plus temozolomide (466 patients), or temozolomide only (229 patients). Patients in either group who experienced cancer progression could also receive second-line chemotherapy. Patients in the TTFields group who experienced cancer progression could continue to receive TTFields treatment. The trial excluded patients with disease progression prior to randomization. Patients who were not able to complete primary treatment and those who could not tolerate temozolomide chemotherapy were also excluded.

The interim analysis of EF-14 trial data was planned to occur when there was at least 18 months of follow-up for the first 315 randomized patients: 210 in the TTFields group, and 105 in the temozolomide-only group.<sup>38</sup> Based on the positive interim results, the trial's data and safety monitoring committee recommended stopping the trial, and TTFields therapy was offered to all patients.

Participants in the EF-14 trial were followed for a median of 40 months and a minimum of 24 months.<sup>30</sup>

### EF-11

In the EF-11 trial, published in 2012, 237 patients with recurrent glioblastoma were randomized to receive either TTFields therapy only (n = 120) or the physician's choice of chemotherapy (n = 117).<sup>39</sup> To be included, patients must have received prior radiation therapy, with or without temozolomide chemotherapy. Patients with implanted medical devices, such as pacemakers, were excluded. Most patients were at the second or third recurrence of the disease. Their assigned treatment began within one week of randomization and continued until their disease progressed further or they were found to be unable to tolerate their assigned treatment. The trial was conducted at 28 centres in the US, Europe, and Israel.<sup>39</sup>

### PRiDe

The Patient Registry Dataset (PRiDe) is a post-marketing registry study following 457 patients with recurrent glioblastoma who received the TTFields therapy in 91 US centres between October 2011 and November 2013.<sup>40</sup> The intent was to gather real-world clinical practice information on patients treated with TTFields. The patients in the registry could have received any prior therapies and could have had any number of cancer recurrences. The median duration of TTField treatment in the registry patients was 4.1 months.<sup>40</sup>

## Overall Survival

In the final analysis of the EF-14 trial, the median overall survival in the intention-to-treat patient groups was 20.9 months in the TTFields-plus-temozolomide group, and 16.0 months in the temozolomide-only group.<sup>30</sup> More than half of the patients in both treatment groups also received second-line drug therapies: 67% of patients in the TTFields-plus-temozolomide group and 57% of those in the temozolomide-only group.<sup>38</sup> At two years after trial enrolment, more of the patients in the TTFields-plus-temozolomide group were alive (43%) compared with the temozolomide-only group (31%).<sup>30</sup>

In the EF-11 trial of patients with disease recurrence, there was no difference in overall survival between the TTFields-only group and the chemotherapy-only group at any time point.<sup>39</sup> Investigators concluded that the EF-11 trial showed that TTFields treatment offered comparable efficacy to that achieved with chemotherapy.<sup>59</sup>

**“In the final analysis of the EF-14 trial, the median overall survival in the intention-to-treat patient groups was 20.9 months in the TTFields-plus-temozolomide group, and 16.0 months in the temozolomide-only group.”**

Authors of the PRiDe registry study also conducted an analysis of survival. Median overall survival was 9.6 months.<sup>40</sup> At one year, 44% of registry patients were alive, and at two years, 30% of patients were alive.<sup>40</sup>

A post-hoc analysis of the EF-11 trial found that median overall survival was higher in patients with recurrent glioblastoma who used the TTFields device for 18 or more hours daily (survival rate of 7.7 months) compared with patients who used the system less (survival rate of 4.5 months).<sup>47</sup>

Researchers at one US centre reported on a small case series that found improved survival in patients who received TTFields treatment in addition to triple-drug therapy (temozolomide, bevacizumab, and irinotecan).<sup>68</sup> Median overall survival was 34.5 months for the 29 patients who received the combined treatment, and was slightly longer — 39.4 months — for the 15 patients who started TTFields treatment earlier (i.e., within 125 days of initial diagnosis).<sup>68</sup>

Another small study, reported in a conference abstract, found that the median overall survival was 12 months in 12 patients who received stereotactic radiosurgery in addition to TTFields therapy,

compared with four months in 28 patients who received TTFields therapy without radiosurgery.<sup>67</sup>

A small case series of eight patients with bevacizumab-refractory glioblastoma reported a median overall survival of 7.2 months from the start of TTFields therapy.<sup>41</sup> Several case reports mention long-term survivors of glioblastoma who have either continued to use TTFields therapy for several years (in addition to drug and other treatments),<sup>12,47,55,69</sup> or who have been in good health and are no longer receiving treatment after receiving TTFields treatment.<sup>47,49,56,70</sup>

## Progression-Free Survival

Progression-free survival is the period of time during and after treatment in which the disease does not worsen. Final EF-14 trial results reported that median progression-free survival in the intention-to-treat patient groups was 6.7 months in the TTFields-plus-temozolomide group, and 4.0 months in the temozolomide-only group.<sup>30</sup>

There was no difference in median progression-free survival at six months in the EF-11 trial patients with recurrent glioblastoma (just over two months in both the TTFields-only group and the chemotherapy-only group).<sup>39</sup>

## Compliance With Treatment

The use of TTFields for 18 or more hours per day is associated with better overall survival.<sup>6,7,30,47,71</sup> At least one continuous 28-day cycle of TTFields treatment is necessary to be able to see a treatment effect (usually based on MRI imaging, if available).<sup>47,48</sup> The Optune system records the amount of time the patient uses the device in a monthly report for the attending physician.<sup>18</sup>

In the EF-14 trial, 75% of the patients in the TTFields-plus-temozolomide group wore the device for an average of 18 or more hours per day.<sup>30</sup>

In the EF-11 trial, of the 116 patients who started TTFields treatment, 78% completed at least one four-week cycle.<sup>39</sup> The average compliance with treatment was 86% (an average of 20.6 hours per day).<sup>39</sup> Twenty-seven patients stopped TTFields treatment early, either because of not using the system for the recommended hours each day or because of an inability to manage the device.<sup>39</sup>

PRiDe registry compliance data were available for only about two-thirds of the patients (n = 287).<sup>40</sup> About 44% of the patients (n = 127) used the TTFields therapy for 18 or more hours per day. Patients with more functional impairment were less compliant in their use of the TTFields treatment.<sup>40</sup>

A small case series of patients with bevacizumab-refractory glioblastoma reported a compliance rate of 74.2%; this was based

on seven of the eight patients' records, with a median duration of TTFields therapy of 5.2 months.<sup>41</sup>

## Quality of Life

Interim EF-14 trial results showed an initial improvement in quality of life in the patients treated with TTFields plus temozolomide, but at the nine-month follow-up there was no difference between the patient groups.<sup>43</sup> Self-reported physical and social functioning were also similar between the groups at the nine-month and the 12-month follow-up.<sup>43</sup> Final EF-14 study results on quality of life are forthcoming.<sup>30</sup>

Data on quality of life was available for 63 patients (27%) in the EF-11 trial who remained on TTFields therapy for at least three months.<sup>39</sup> These patients reported a higher quality of life — including better cognitive and emotional status — than those in the chemotherapy group, possibly because they were not experiencing the toxic effects of chemotherapy.<sup>11</sup> There was no difference between the groups in the domains of overall health and social functioning.<sup>39</sup>

## Safety

### Skin Irritation

The most common adverse event with the use of TTFields therapy is skin irritation, including rash, ulceration, and infections.<sup>19,21,72</sup>

The irritation is mainly due to repeated shaving of the scalp, application and removal of the transducer arrays, allergic reaction to the hydrogel, and the pressure of the transducers on the skin.<sup>14,19</sup> Skin irritation was usually mild to moderate, and it was treatable with topical steroids or antibiotics and by slightly adjusting the positioning of the transducer arrays and adhesives when they were exchanged. It was also treated by removing the arrays for a few days.<sup>19,72</sup>

In the EF-14 trial, about 52% of patients in the TTFields group had mild to moderate skin reactions, and about 2% of patients had more severe skin reactions.<sup>30</sup> Patients in the TTFields-plus-temozolomide treatment group reported "itchy skin" more often than those in the temozolomide-only group.<sup>43</sup> In the EF-11 trial, 16% of patients in the TTFields group experienced mild to moderate skin irritation.<sup>39</sup>

In the PRiDe registry, 24.3% of patients (the actual patient numbers were not reported) experienced skin reactions.<sup>40</sup> Although some patients reported a sensation of scalp warmth, this did not cause injury.<sup>40</sup> (When the device is in operation, sensors in the arrays monitor temperature. The system sounds an alarm and automatically shuts off if the temperature rises above 105.8°F or 41°C.<sup>19</sup>)

## Systemic Adverse Events

In the EF-14 trial, systemic adverse events such as blood and gastrointestinal disorders, seizures, and infections were similar in the patients who received TTFields plus temozolomide, and those who received temozolomide only.<sup>30</sup> In the EF-11 trial, systemic adverse events such as gastrointestinal and blood disorders, and infections, occurred more frequently in the chemotherapy patient group.<sup>39</sup>

A post hoc analysis of 144 patients in the EF-14 trial who received TTFields in addition to second-line drug therapies after disease recurrence found a higher incidence of adverse events compared with patients who received chemotherapy only.<sup>51</sup> These results may have been confounded by the second-line drug therapies used (most commonly bevacizumab), the longer follow-up period for patients who received TTFields, and the 14 patients who crossed over to the TTFields treatment arm who had not initially received TTFields.<sup>51</sup>

**"The most common adverse event with the use of TTFields therapy is skin irritation, including rash, ulceration, and infections."**

### Other Adverse Events

Other adverse events reported in the registry patients included neurological disorder (10.4%), seizure (8.9%), headache (5.7%), pain or discomfort (4.7%), and falls (3.9%). Actual patient numbers were not reported.<sup>40</sup>

In the EF-14 study, the rates of seizures were similar in the patients who received TTFields plus temozolomide and those who received temozolomide only.<sup>30</sup>

TTFields therapy should not be used in patients with active implanted devices — such as deep brain, spinal cord, or vagal nerve stimulators; or pacemakers — or in individuals with a sensitivity to the conductive hydrogels.<sup>25,26,61</sup> A 2017 laboratory study concluded that radiation therapy should not be used when the transducer arrays are in place because of an increased risk of skin toxicity.<sup>50</sup>

## Cost Studies

No Canadian economic evaluations were identified.

French researchers examined the cost-effectiveness of TTFields therapy in patients newly diagnosed with glioblastoma based on interim data from the EF-14 trial.<sup>29</sup> Two scenarios were considered: the first, standard of care alone, which included radiation therapy and temozolomide; and the second, TTFields treatment plus standard of care. With a projected life expectancy

of 22.08 months in the TTFields scenario and 18 months in the standard of care alone scenario, TTFields therapy costs €243,141 compared with €57,665 for standard treatment alone; with an incremental cost-effectiveness ratio (ICER) of €549,909 per life-year gained.<sup>29</sup> A Swedish cost-effectiveness evaluation using more recent patient data has also been conducted; however, the results are not available in English.<sup>73</sup>

A systematic review of economic studies assessing the cost-effectiveness of glioblastoma therapies, including TTFields therapy, is underway at the University of York and expected to be published in 2018.<sup>74</sup>

## Concurrent Developments

### Treatments for Glioblastoma

Molecular-based tumour typing is increasingly important in cancer diagnosis and treatment decisions.<sup>75,76</sup> People with glioblastoma tumours that have particular genetic alterations have better prognoses than those with tumours having only some or none of these alterations.<sup>75</sup>

Many clinical trials for glioblastoma therapies are in various phases of development.<sup>77-79</sup> Some researchers have speculated there may be a synergistic effect between TTFields therapy and the response to drug therapies.<sup>42,57,62</sup> Clinical trials of TTFields therapy in combination with other therapies are also in progress.<sup>8,17,80</sup>

Immunotherapies, vaccines, and oncologic viruses that promote the patient's immune system response or target tumour cells are other areas of investigation.<sup>76,77,81-83</sup> Glioblastoma is one of the cancers included in chimeric antigen receptor (CAR) T-cell therapy research — where a patient's T-cells are extracted, genetically modified, and reinfused to attack cancer cells.<sup>78,84,85</sup>

Ultrasound technologies, such as microbubbles that temporarily allow better access of drug therapies across the blood-brain barrier, and focused ultrasound ablation (or removal) of tumours have also been investigated in the treatment of glioblastoma.<sup>5,86,87</sup>

Another device-based treatment for glioblastoma is the Nativis Voyager (Nativis, Seattle), which is undergoing feasibility and safety trials in the US and Australia.<sup>88,89</sup> The Nativis Voyager is worn on a headband and the device delivers ultra-low radiofrequency energy to the brain. The radiofrequency energy is believed to disrupt genetic processes in the cancer cells — in particular, the epidermal growth factor receptor — and prevent cell division.<sup>89</sup>

### Other Uses of Tumour-Treating Fields

Small studies of TTFields in treating other types of cancers have also been published or are underway, including investigations of its use in meningioma — a brain tumour that forms on the membranes covering the brain and spinal cord; brain metastases from other types of cancer; mesothelioma (a rare cancer related to asbestos exposure); and pancreatic, lung, and ovarian cancers.<sup>8,11,13,17,36</sup> A Danish trial is investigating the feasibility of increasing TTField intensity to the tumour by craniectomy — removing small pieces of the overlying skull.<sup>52</sup>

A report of compassionate use of TTFields treatment in five children and adolescents with high grade gliomas (including glioblastoma) concluded a pediatric trial would be worthwhile,<sup>90</sup> and the Pediatric Brain Tumor Consortium is conducting a trial in children.<sup>91</sup>

## Implementation Issues

### Uptake

A 2017 US review noted that uptake of TTFields treatment has been relatively slow, and that only about 15% of patients newly diagnosed with glioblastoma were treated with TTFields in 2016.<sup>7</sup> Worldwide, over 5,000 patients with glioblastoma have been treated with TTFields (Justin Kelly, Novocure, Portsmouth, NH: personal communication, 2017 Oct 30).

### Training Needs

Originally, Novocure clinical staff customized the layout of the transducer arrays for each patient.<sup>92</sup> Now, physicians who prescribe Optune must receive training and certification to do this for their patients using the NovoTAL System.<sup>33,92,93</sup> A study involving 14 physicians (neuro-oncologists, medical oncologists, and neurosurgeons) certified to prescribe Optune found that physicians in all specialties were able to use the system to accurately initiate and adjust patient treatment.<sup>92</sup>

Patients and their families or caregivers also need training in using the device and in scalp preparation, and in ensuring the correct placement of the transducer arrays.<sup>1,7,14</sup>

### Caregiver Burden

Cleansing and shaving the scalp, replacing the electrodes every three days, and wearing the device for most of the day and night may be a burden for some patients.<sup>7</sup> Most patients will need help to prepare their scalp and apply the arrays, and family or caregiver support will likely be needed.<sup>7,22,59</sup>

## Patient Perspective

The need to shave the head and wear the noticeable transducer arrays and wires may be seen as a stigma of cancer, as with hair loss in chemotherapy.<sup>7,16,63,65,94</sup>

Jeffrey Weiss, a US journalist with glioblastoma who has since passed away, chronicled his experience as a patient with this disease, including his experience using the TTFields therapy:

"Optune use is a real-world physical hassle. Four palm-sized patches of electrodes are stuck to my scalp in a particular pattern. Every two days, the electrodes must be removed, my scalp cleaned and reshaved, and a new set of electrodes stuck on. (My wife, Marni, has to do the electrode installation; I can't possibly reach all around my head to get them on correctly.) Sweat is a problem. It can make the electrodes fall off. Heat is a problem; if my head gets even a bit warm, an alarm goes off. When I leave the house, I wear hats to cover the odd-looking electrode patches..."<sup>95,96</sup>

One investigator with the EF-14 study noted that patients:

"...became psychologically dependent on the TTFields device, and saw it as a tangible way to treat their own disease. They were responsible for wearing the device, taking it with them throughout the day, and recharging the batteries. They also had to change their transducer arrays every few days..."<sup>61</sup>

This is in contrast to other cancer treatments where patients are more passive recipients of care.<sup>22,61</sup> As one US patient who has used the system for two years said: "I wear it and wear it proudly... It's an incredible machine and I'm fine not having hair."<sup>97</sup>

Some patients found the system cumbersome, but future design modifications are expected.<sup>8,62</sup> A 2016 conference abstract, reporting one centre's experience with providing TTFields therapy, described the following reasons patients gave for not using the system: inability to tolerate the side effects (not specified), lack of caregiver support, and impact on lifestyle.<sup>98</sup> In addition, two patients did not start TTFields therapy as prescribed because of social or financial reasons.<sup>98</sup>

## Patient Education

Health care providers will need to educate patients and their families about the importance of compliance, as the effectiveness of TTFields depends on the device being worn and turned on.<sup>7,22,47</sup> A recent guide for nursing staff noted that some patients experience cognitive impairment as a result of their disease treatments, so that user errors — such as not noticing the device was not turned back on after a break in therapy — may occur, which can affect compliance.<sup>22</sup> The device's compliance report

for physicians may help to identify these types of issues.<sup>22</sup> In addition to supporting the health care professionals, Novocure technicians are available to provide technical support to patients and caregivers.<sup>22</sup>

## Patient Selection

It is not yet clear which patients with glioblastoma are most likely to benefit from TTFields treatment.<sup>16,17</sup> The distribution of the electrical fields to the tumour is affected by many variables in addition to the positioning of the transducer arrays, including the location and shape of the tumour and whether it contains a core of necrotic (or dead) tissue, the layer of cerebrospinal fluid, and the insulating properties of adjacent tissue.<sup>99</sup>

**"The cost of TTFields therapy will be a barrier for patients if this therapy is not covered by public and private health insurance."**

Preliminary evidence suggests that patients who may benefit most are those:

- with tumours that are more superficial, rather than those located deep within the brain.<sup>100</sup>
- who have not previously received bevacizumab. These patients may have a better prognosis.<sup>40,64</sup> However, a small subgroup analysis also suggested that patients who have developed resistance to bevacizumab may have a better response to TTFields therapy — possibly because of an altered immune response after receiving bevacizumab.<sup>47</sup>
- with tumours that developed from lower grade gliomas. These tumours appear to have a better response to TTFields therapy.<sup>45</sup> As primary and secondary glioblastomas differ genetically, in the future, the genetic profiling of tumours may allow for better identification of patients who will benefit from TTFields treatment.<sup>45</sup>

## Imaging Needs

Planning the patient's transducer array layout is based on existing MRI imaging taken as part of standard care for glioblastoma (Justin Kelly, Novocure, Portsmouth, NH: personal communication, 2017 Oct 30). Subsequent MRIs, every two to three months, are also part of standard follow-up for patients with glioblastoma.<sup>14</sup> For a more accurate assessment of treatment response in glioblastoma, investigators are exploring advanced MRI-based techniques, such as diffusion tensor imaging, 3-D echo-planar spectroscopy, and dynamic susceptibility contrast perfusion-weighted imaging.<sup>54,101</sup>

## Pseudoprogression

In patients with glioblastoma, pseudoprogression (transient visual changes in the tumour not indicative of true disease progression), commonly due to tissue necrosis from radiation therapy, is often seen on follow-up MRIs within the first months after chemotherapy and radiation treatment.<sup>14,31,102</sup> There is also a delay between treatment response with TTFields and when this becomes evident on MRI images.<sup>14</sup> Continuation of TTFields treatment is recommended, regardless of early diagnostic imaging results.<sup>7,48,49,70,93</sup> The effects of a prolonged use of TTFields after cancer recurrence — for example, on slowing the rate of progression or on tumour regression — warrant further investigation.<sup>16</sup>

## Other Issues

The cost of TTFields therapy will be a barrier for patients if this therapy is not covered by public and private health insurance.<sup>7,23</sup>

The reduced incidence of systemic adverse events with TTFields therapy for patients with recurrent glioblastoma may reduce health care costs associated with treating more serious adverse events caused by chemotherapy and radiation therapy.<sup>8</sup> A 2012 Australian health technology assessment of TTFields therapy included unpublished manufacturer's information that found fewer hospitalizations and reduced length of stay among the patients who received TTFields treatment compared with those who received best standard chemotherapy.<sup>103</sup>

In the US, the Novocure support technicians meet with patients each month to provide support and download the compliance report for the health care team.<sup>22</sup> How this works for patients outside of the US is not clear.

## Final Remarks

In September 2017, Novocure announced that the German Federal Joint Committee, the Gemeinsamer Bundesausschuss, will jointly fund a new trial to assess the benefit of starting TTFields treatment earlier — as part of initial therapy alongside radiation therapy and temozolomide.<sup>104</sup>

Treatments that may improve survival without negatively affecting quality of life are important for patients with this aggressive, difficult-to-treat cancer.<sup>43</sup> Nevertheless, some clinicians remain skeptical about the benefits of TTFields — perhaps because it is so different from traditional cancer treatments.<sup>7,16,23,63</sup> Further research is underway that may clarify the place of TTFields in the treatment of glioblastoma.

# A review on Tumor Treating Fields (TTFields): Clinical implications inferred from computational modeling

Cornelia Wenger, Pedro C. Miranda, Ricardo Salvador, Axel Thielscher, Zeev Bomzon, Moshe Giladi, Maciej M. Mrugala and Anders R. Korshøj

**Abstract**—Tumor Treating Fields (TTFields) are a cancer treatment modality that uses alternating electric fields of intermediate frequency (~100-500 kHz) and low intensity (1-3 V/cm) to disrupt cell division. TTFields are delivered by transducer arrays placed on the skin close to the tumor and act regionally and non-invasively to inhibit tumor growth. TTFields therapy is FDA approved for the treatment of glioblastoma multiforme, the most common and aggressive primary human brain cancer. Clinical trials testing the safety and efficacy of TTFields for other solid tumor types are underway.

The objective of this article is to review computational approaches used to characterize TTFields. The review covers studies of the macroscopic spatial distribution of TTFields generated in the human head, and of the microscopic field distribution in tumor cells. In addition, pre-clinical and clinical findings related to TTFields and principles of its operation are summarized. Particular emphasis is put on outlining the potential clinical value inferred from computational modeling.

**Index Terms**—Computational Modeling and Simulation, Finite Element Models, Cancer Treatment, Tumor Treating Fields

## I. INTRODUCTION

### A. Electric field interactions with biological tissue

It is well established that electric fields (EFs) affect cellular function. Direct current or low-frequency alternating fields (<1 kHz) affect the polarization of cell membranes [1] and induce excitatory or inhibitory effects on electrically excitable tissue. Thus, medical applications utilizing low frequency fields target a multitude of diseases in a range of tissues including neural and muscle tissue [1]. High frequency fields

(MHz range) do not induce membrane polarization but rather cause fast oscillation of polar molecules (friction) [2] leading to tissue heating. Therefore high frequency electromagnetic fields are used for applications, such as diathermy and tissue and tumor ablation [3]. Until recently the intermediate frequency range of several hundred kHz had not been considered for medical applications, since currents in this range alternate too fast to stimulate nerves or muscles and induce only minute heating through ohmic and dielectric loss [4]. However, since the early 2000's, several studies have shown that intermediate frequency fields disrupt cell division in cancer cells [5], [6]. These observations have led to the development of Tumor Treating Fields (TTFields) [5], [6], a physical modality for treating cancer.

### B. TTFields: pre-clinical observations and mechanisms of action

TTFields are alternating EFs in the frequency range of 100-500 kHz and intensities typically in the range 1-3 V/cm [5] that exert an anti-mitotic effect on cells. TTFields have been studied *in vitro* using several preclinical laboratory research systems that have been developed for this purpose. These systems include, the Inovitro™ system (Novocure Ltd.), [7] which consists of a TTFields generator connected to a set of ceramic petri dishes, microfluidic devices [8] and wire based devices [5], [9], [10]. Using these types of devices, researchers have shown that exposing cells to TTFields leads to prolonged mitosis, the formation of abnormal mitotic figures and mitotic cell death [5], [11], [12]. TTFields also induce violent membrane blebbing during telophase, which in turn leads to the formation of abnormal daughter cells and induction of cell death in the following interphase [5], [13]. The anti-mitotic effect of TTFields is synergistic with the effects of chemotherapeutic agents [14]–[16]. When combined with TTFields, chemotherapeutic agents delivered at doses well below the therapeutic threshold lead to complete cell cycle arrest [14]. Pavesi et al. (2016) showed that TTFields application leads to reduced proliferation of breast cancer cells, whilst leaving normal human endothelial cells largely unaffected [8]. Recent studies have also demonstrated that TTFields can inhibit cell migration [9] and DNA damage repair [10], [17].

TTFields effect is intensity dependent. Cell growth rate decreases as field intensity increases. For most cell lines, growth rates begin to decrease when the field intensity

This research was supported in part by the Fundação para a Ciência e Tecnologia (FCT) in the scope of the FCT-IBEB Strategic Project UID/BIO/00645/2013.

exceeds a threshold of about 1 V/cm, and growth is completely arrested when field intensity exceeds about 2.5 V/cm [5], [6]. The effect is also frequency dependent, and each cell line has an optimum frequency, at which the inhibitory effect on cell growth is most significant [5], [6]. For glioma cells the optimal frequency is 200 kHz [5], [6]. In addition, cells dividing parallel to the field are more likely to be affected by the field than cells dividing in other directions [6], and periodically switching the field between two orthogonal field directions was shown to be 20% more effective compared to applying TTFIELDS in a single direction [6]. Finally, cells with a short doubling time are more susceptible to the effect TTFIELDS [12], likely due to the higher frequency of mitotic events in a given time.

It has been proposed that TTFIELDS exert their effect by causing alignment of proteins with large dipole moments with the EF [5], [6], thereby disrupting structures and inhibiting protein polymerization. Indeed, two proteins with large dipole moments, tubulin dimers (1740 Debye – [18]) and septin (2711 Debye–[13]) are affected by TTFIELDS. Studies show that TTFIELDS disrupt microtubule (MT) polymerization, preventing proper chromosome segregation during mitosis [12], and that under the influence of TTFIELDS, septin, which serves as scaffold for the actin myosin ring closing the cytokinetic furrow, fails to localize to the cell mid-zone leading to ectopic blebbing and abnormal mitosis [13].

To explain the effect of TTFIELDS, it has also been suggested that when TTFIELDS are applied to cells during telophase, the hourglass shape of the dividing cell causes the EF within the cell to become highly non-uniform with higher field intensities close to the narrow furrow region. Such field inhomogeneity results in dielectrophoretic (DEP) forces [19] possibly leading to irregular aggregation of polarizable particles, thereby disrupting cell division [4], [5].

These two theories were recently evaluated in a theoretical analysis by Tuszyński et al. [20]. According to this analysis, the DEP forces that develop during telophase are indeed strong enough to interfere with mitosis. However, the forces and torques that the EF exerts on the intrinsic dipoles of tubulin are too small to have a significant effect on tubulin alignment. This analysis demonstrates that although the biological effects of TTFIELDS on cells are well-documented, there is still a need for in-depth biophysical studies to elucidate the physical mechanisms by which TTFIELDS exert their biological effects [21].

### C. TTFIELDS: clinical trial and clinical settings

The clinical application of TTFIELDS has been tested in animal models [5]–[7], [11], [22], [23] and several clinical trials, the first of which demonstrated that exposure to TTFIELDS led to local regression of skin metastases from breast cancer and melanoma [24]. A pilot trial with patients suffering from glioblastoma multiforme (GBM) showed that treatment with TTFIELDS is feasible and well tolerated without causing serious adverse effects [25]. A subsequent phase III clinical trial (EF-11) compared the efficacy of TTFIELDS to the physician's best choice of chemotherapy in recurrent GBM

patients [26]. This trial showed comparable efficacy between the two arms with a better quality of life and less toxicity for TTFIELDS patients [26] leading to the US Food and Drug Administration (FDA) approving TTFIELDS for the treatment of recurrent GBM in 2011. The subsequent EF-14 trial showed that treating newly diagnosed GBM patients with a combination of TTFIELDS and temozolomide led to a 5 month increase in median overall survival (hazard ratio 0.65,  $p < 0.00005$ ) relative to patients treated with temozolomide alone [27]–[29]. TTFIELDS combined with temozolomide was approved by the FDA for the treatment of newly diagnosed GBM in October 2015.

Clinical trials testing feasibility and safety and/or efficacy of applying TTFIELDS to non-small cell lung cancer (Lunar – [30], [31]), pancreatic (Panova – NCT01971281 [32]), ovarian cancer (Innovate - NCT02244502), mesothelioma (Stellar-NCT02397928), and brain metastasis (Metis - NCT02831959, Comet - NCT01755624) have also been initiated.

When treating GBM, TTFIELDS are delivered using the Optune™ system (Novocure Ltd). The system weighs 1.3 kilograms and comprises a portable battery powered field generator, which is connected to two pairs of transducer arrays placed on the shaved scalp of the patient. One pair of arrays is placed on the left and right sides of the head (LR array), and the other pair on the anterior and posterior aspects of the head (AP array). Each array consists of 9 ceramic disks arranged in a 3x3 configuration [33]. The device delivers a maximum current of 2000 mA peak-to-peak at a frequency of 200 kHz. At any given instance, the current is delivered to only one pair of arrays, and the direction of the field is switched between the pairs of arrays once per second. Patients are treated outside the hospital environment and advised to wear the device for a minimum of 18 hours per day to ensure effective treatment [33]. The transducer arrays are disposable and replaced every few days [33], [34]. The same principles apply to treatment of other body regions, with the frequency of the field and the geometry and positioning of the transducer arrays adapted for each application. For instance, in clinical trials, lung cancer is treated using the NovoTTF-100L™ device, which delivers TTFIELDS at 150 kHz and is configured with larger transducer arrays than the Optune device [31], [35].

The placement of Optune™ transducer arrays on the patient's scalp (referred to as layout) is determined using the NovoTAL™ system [36], [37]. NovoTAL™ uses measurements of the head and tumor obtained from axial and coronal MR images of the patient to derive array layouts that maximize the field delivery to the tumor. Treatment planning with NovoTAL™ was defined as part of the protocol for the EF-14 trial, and is standard when initiating TTFIELDS treatment [36]. Computational studies have shown increased EF delivery to the diseased region [38], [39] when arrays are adapted to the individual tumor location.

### D. Article motivation and purpose

Many factors are known to influence the outcome of GBM treatment. These factors include: age, Karnofsky performance status (KPS), the extent of the resection, and morphological,

histological and genetic characteristics, such as IDH and MGMT tumor mutation status [40], [41]. When treating with TTFields, it is reasonable to assume that in addition to the factors mentioned above [21], the distribution and intensity of the induced EF in the brain and tumor also influence treatment outcome. The field distribution and intensity may vary significantly between individuals depending on the size, shape and electrical properties of the head, brain and tumor. It would be highly desirable to measure the field intensities in the regions of interest. However presently this task remains challenging. Hence, numerical simulations are the best available tool for evaluating TTFields distributions within patients.

In this paper we will review computational studies analyzing the application of TTFields. We will show how modelling TTFields at the cellular level can be used to investigate the biophysical basis for TTFields mechanisms of action, and how realistic human head models can be used to investigate the connection between EF distribution and efficacy and safety of TTFields treatment. We will discuss how, in the future, these models could be employed to study treatment response, predict progression patterns, conduct retrospective outcome analysis, enable prospective personalized treatment planning, and possibly help to select suitable candidates for therapy

## II. COMPUTATIONAL MODELS OF TTFIELDS

Whether simulating TTFields delivery at the cellular scale (section 2.1) or at the full head scale (section 2.2), the EF distribution is approximated by applying volume conductor models [1] to numerically solve derivatives of Maxwell's equations of electrodynamics with appropriate boundary conditions (BCs). For TTFields, the electromagnetic wavelength is much larger than the size of the models, and therefore the electro-quasistatic approximation of Maxwell's equations may be applied [42]. Thus, the electric potential  $V$  can be found by solving the Laplace equation,  $\nabla \cdot \tilde{\sigma} \nabla V = 0$ . Here  $\tilde{\sigma} = \sigma + i\omega\epsilon$  is the complex conductivity  $\epsilon$  is the permittivity,  $\sigma$  the electrical conductivity and  $i$  the imaginary unit, and  $\omega = 2\pi f$  the angular frequency. The numerical task of solving the Laplace equation can be achieved using for example, the finite element (FE) method. Table 1 illustrates the similarities and differences between cellular scale and full head scale models for studying TTFields.

### A. Cellular level modeling

#### 1) Materials & Methods

Glioma cells have been found to round up during mitosis to a sphere of approximately 5500 fL (radius of approximately 11  $\mu\text{m}$ ) [43]. According to images of the division process [43], as the cell proceeds into telophase elliptical cell shapes with equal size become more appropriate to characterize the process in which the daughter cells form.

To reflect these geometries, studies simulating TTFields application to single cells [20], [44]–[46] assumed a spherical cell with a default radius of 10  $\mu\text{m}$  during metaphase. During

telophase and cytokinesis, elliptical sister cells with a default major radius of 10  $\mu\text{m}$  and minor radius of 7  $\mu\text{m}$  were considered. Three different stages of telophase were modelled by decreasing the length of the incision plane between the sister cells (furrow length) as division progressed (red line in bottom panel of Fig.1).

The models comprised three domains: the extracellular space, the cytosol and the membrane, which differ in their dielectric properties. The standard values assigned to these tissue types were:  $\sigma_i = 0.3$  S/m,  $\sigma_e = 1.2$  S/m,  $\sigma_m = 3e-7$  S/m,  $\epsilon_i = 72.3$ ,  $\epsilon_e = 72.3$ ,  $\epsilon_m = 5$ . These values were adapted from computational studies conducting similar investigations [47]–[56]. Since a large range of properties are expected within the population of glial cells [46], different ranges of these parameters were tested to investigate how the dielectric properties of cells influence their response to TTFields (section 2.1.2). The computational studies [20], [44]–[46] were carried out using the Electric Currents Interface of the AC/DC module of Comsol Multiphysics (www.comsol.com). The thin membrane was numerically represented by the contact impedance BC available in Comsol.

In order to apply a homogenous EF the BCs on two opposite sides were chosen as terminals of the voltage type where the others were electrically insulated, representing an ideal parallel plate electrode setup. The default applied voltages of opposite signs were chosen to produce standard field intensity of 1 V/cm, which corresponds to the minimum activity threshold of TTFields intensity. The computational model was validated by comparing numerical results for a spherical cell to the analytical description of the transmembrane voltage of a spherical cell with radius  $r$  (data not shown) [52].

### 2) Results

#### a) Effect of field frequency

The distribution of the EF intensity in and around a cell with standard geometric and dielectric properties (section 2.1.1) is plotted in Fig.1 for selected frequencies (rows) at different stages of mitosis (columns). For a round cell during metaphase the EF distribution inside the cell is uniform with only small perturbations close to the membrane. The intracellular field intensity,  $E_i$  almost equals zero for frequencies <10 kHz (left top in Fig.1, Fig.2). For increasing

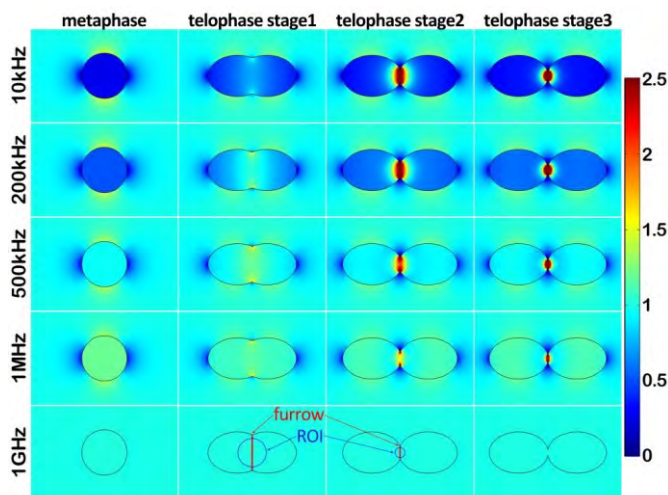

Fig. 1.  $E_i$  distribution in the metaphase cell (column1) and three stages of telophase (columns 2-4) for varying frequency (rows) of the applied EF from left to right with an intensity of 1 V/cm. The color scale is fixed for all panels from 0 - 2.5 V/cm. The bottom panel illustrates the furrow length (red line) and spherical ROI (blue circle) in the telophase cells.

frequency,  $E_i$  gradually increases and finally equals the applied field intensity for frequencies  $>1$  GHz as predicted by Fig.1-2 and discussed in detail elsewhere [45], [46].

During telophase, the low frequency fields do not penetrate the membrane and  $E_i$  is close to zero (column 2 in Fig.1, Fig.2). However, as frequencies increase into the kHz range, a non-uniform field develops within the cytosol with higher field intensities found close to the furrow between the dividing cells (columns 2-4 in Fig.1). The most pronounced and spatially confined EF at the furrow is found for a stage3 cell (column 4 in Fig.1). As the frequency of the field increases, the non-uniformity close to the furrow decreases and the field intensity throughout the cell increases. Thus,  $E_i$  peaks between 100-500 kHz during telophase, with lower peak frequencies observed for later stages of cell division (Fig.2).

For this review article, we evaluated the maximum of  $E_i$  in a spherical region of interest (ROI – blue circles in bottom panel of Fig.1) located at the center of each cell, with a diameter that corresponds to 80% of the furrow length (Fig.2). The figure shows that the maximum value of  $E_i$  increases as the cell

Fig. 2. Maximum  $E_i$  as a function of frequency for 4 different cell cycle stages. The values are measured in central ROIs with a radius of 80% of the furrow length.

progresses through cell division and that its value can exceed the external field strength of 1 V/cm. Secondly, the frequency for which the maximum  $E_i$  occurs decreases as cell division progresses (Fig.2). As a result of the field inhomogeneity inside the dividing cell, the gradient of the EF becomes non-zero. Hence the DEP force component defined as  $\nabla|E_i|^2$  [57], [58] also takes on non-zero values, increasing to maximal values during later stages of telophase with highest values for stage3.

#### b) Effect of cell size

Subsequently, we investigated how the geometric and dielectric properties of the cell influence the EF distribution. Figure 3 shows the maximum of  $E_i$  as a function of frequency for cell radii  $r=\{4,10,15,20\mu\text{m}\}$ . During metaphase the biggest cell with  $r=20\mu\text{m}$  has the highest  $E_i$  for all field frequencies, (Fig.3A), and the peak frequency at which the highest  $E_i$  is found in a cell (10 MHz) is unaffected by cell radius. During telophase the biggest cell has the highest  $E_i$  only for low

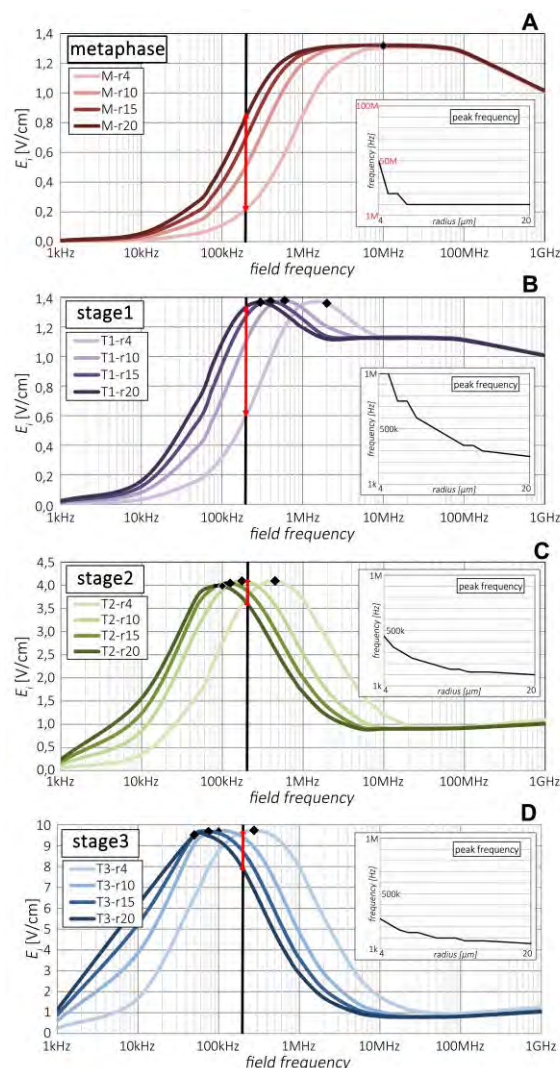

Fig. 3. Maximum  $E_i$  as a function of frequency for 4 selected cell sizes (A) during metaphase and different stages of telophase (B-D). The insets in (B-D) plot the peak frequency as a function of cell radius, corresponding peaks of the 4 selected cells are marked as black diamonds on the curves. The vertical line marks 200 kHz and the span of values is emphasized in red.

frequencies (Fig.3B-D). As the cell radius increases, maximum values of  $E_i$  occur at lower frequencies (insets of Fig.3B-3D). When a constant field frequency of 200 kHz is applied, cell size influences the field exposure inside the cell (vertical lines in Fig.3). During metaphase and stage1 (Fig.3A-B), the highest  $E_i$  is found in the biggest cell and the lowest  $E_i$  in the smallest cell, whereas for stage2 and stage3 the maximum  $E_i$  is found in cells of smaller size (Fig.3C-D).

It is interesting to note that the differences in the maximal values of  $E_i$  obtained at different cell sizes are smaller than 3%, as shown by the similar height of curves in Fig.3 and the dotted lines in Fig.4. This might suggest that the effect of TTFields can be maintained if the frequency is tuned to match the cell size. However, the simulations show that the magnitude of the DEP force component  $|\nabla|E_i|^2|$  is inversely proportional to cell size, likely leading to less effective exposure for bigger cells (solid lines in Fig.4).

Fig. 4. For each tested cell radius ( $r=4\text{--}20\mu\text{m}$ ), the normalized maximum of  $|\nabla|E_i|^2|$  is plotted as solid lines (left primary axis) and the maximum of  $E_i$  as dotted lines (right secondary axis). Values measured in central ROIs.

#### c) Effect of cell's dielectric properties

Previous computational studies predicted that the dielectric properties,  $\sigma$  and  $\epsilon$ , of the cell are important determinants of the values of  $E_i$  and  $|\nabla|E_i|^2|$ . The most influential parameters were found to be  $\sigma_i$ ,  $\sigma_m$ , and  $\epsilon_m$ , details can be found in [45], [46]. For all parameter variations, peak frequencies varied between 125 kHz-1 MHz for stage1, 50 kHz-400 kHz for stage2, and 50 kHz-250 kHz for stage3. Another consequence of changing the cells dielectric parameters is that for a fixed field frequency of 200 kHz, induced values of  $E_i$  and  $|\nabla|E_i|^2|$  might differ significantly.

Apart from the cell's intrinsic geometric and dielectric properties, the intensity and direction of the externally applied EF influence the EF distribution inside and around the cell. The induced values of  $E_i$  increase proportionally with increasing field intensity and the DEP force component exhibits a quadratic growth [44].

#### d) Effect of cell orientation

The connection between the orientations of dividing cells relative to the field has also been investigated. The field's orientation to the spherical metaphase cell does not change  $E_i$ . The intracellular field remains uniform with parallel EF lines perpendicular to the applied field. But when the cell shape becomes irregular during telophase, the angle between the division axis of the cell and the applied field has significant impact on the intracellular field distribution. The higher the angle between the furrow and the field, the lower the induced maximum  $E_i$  within the cell. This is true for frequencies below 1 MHz, after which the behavior is reversed (results not shown). As example Fig.5, plots the field distribution at 200 kHz for the 3 stages (columns) and 5 different angles from  $0^\circ$  to  $90^\circ$  (rows). The decreasing maximum values within the spherical ROIs (white circle in Fig.5) are printed in the panels. Furthermore, the average EF within the whole cells also decreases (black values in Fig.5). In each column the  $E_i$  in the highly exposed furrow region diminishes as the angle between division axis and field increases from top to bottom.

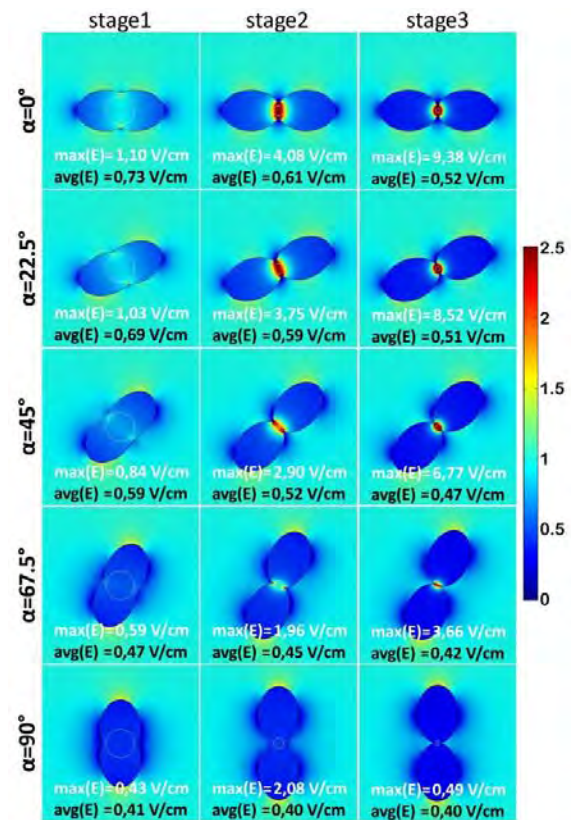

Fig. 5.  $E_i$  distribution induced in a cell during 3 stages of telophase (columns) for varying angle between the division axis and the EF (rows). The field has a frequency of 200 kHz, an intensity of 1 V/cm, and it is applied from left to right. The maximum  $E_i$  in a spherical ROI (white circle) is presented in each panel in white, and the corresponding average  $E_i$  in the whole cell in black.

#### e) Discussion and Future Directions

The ultimate goal of the computational models presented above is to provide insight into the biophysical mechanisms that govern TTFields, starting with the examination of the connection between the intracellular field distribution and the

field parameters (mentioned in section 1.2) that influence treatment efficacy.

**Field frequency:** Experimental results predict that the efficacy of TTFields is frequency dependent and each cell line has a specific frequency for which the inhibitory effect is highest [5]. Additional *in vitro* experiments predict that the optimal frequency for inhibitory effect of TTFields is inversely related to cell size [5], [6]. The computational models confirm that during cell division, the EF intensity peaks in the range between 100-500 kHz with a lower peak frequency for later stages of telophase (Fig.2). It should be noted that the target cells are all in different stages of mitosis in a patient, and therefore there is probably no single frequency that is optimal for all of the cells. However, even if one were to be able to synchronize the target cells to be in stage3 for instance, it might not increase the therapeutic effect of TTFields delivered at a single frequency because of potentially other yet undiscovered biological processes.

The computational models further predict that the cell's geometric (Fig.3) and dielectric properties influence the reported peak frequencies. Because different cell lines have different properties, the simulation results might explain the cell-line specific optimal frequency. It would be insightful to evaluate and measure the size and dielectric properties of different cell lines [59] and compare them to the computational results. The modeling results show that with increasing cell size the peak frequencies decrease (insets Fig.3B-D). The corresponding maximum values of  $|\nabla|E_i|^2|$  also decreases with cell size. It is worth noting that experiments showed that cell volume increases in almost all cell lines treated with TTFields [60]. Thus, increasing cell size during TTFields treatment might be an escape mechanism of the cancer cells, because the intracellular field and DEP component decrease as cell size changes.

**Field Intensity:** TTFields' effect increases with intensity [5], and higher field intensities yield smaller cell counts. The computational modeling confirms that increasing the field's intensity also increases the induced intracellular field and DEP component [44]–[46].

**Direction of division:** In line with experimental results, the computational model predicts decreased intracellular field strengths for cells that are not dividing parallel to the applied field.

When evaluating these results it is important to keep in mind that the models represent single isolated cells with a homogeneous cytoplasm. Yet, within tissue, cells are generally packed, which could cause local inhomogeneity in the extracellular fields, and could to some extent attenuate field distributions. However, the degree to which TTFields penetrate the cells is determined by the properties of the single cell. Thus, it is unlikely that the observation that the intracellular field and DEP depend on the frequency, intensity and direction of the applied field will change when considering models of packed cells. Additionally, the cytoplasm is heterogeneous and contains multiple organelles which would increase the non-uniformity of intracellular

fields. This could possibly lead to local field gradients and DEP forces even when the cell is rounded during metaphase. Thus cytoplasmic heterogeneity is expected to magnify the effects of TTFields.

Let's now turn our attention to how the intracellular EF might disrupt mitosis. Endogenous EFs are believed to play a key role during mitosis [61], [62] as supported by experimental evidence for peak electromagnetic activity during mitosis [63], [64] as well as by physical modeling of the electrostatic forces generated by MTs which are at work during mitosis and influence chromosomal motion [65]–[67]. Thus, it is not unlikely that external electric fields, such as TTFields could disrupt mitosis. It has been speculated that when dividing cells are exposed to TTFields, the tubulin dimers align with the field rather than with the growing MT axis. However, Tuszyński et al. [20] calculated that the interaction energy of a tubulin dimer with an EF of 1 V/cm is too small to affect the dynamics of the dimer. They also proposed that a 1 V/cm EF would be insufficient to exert a major influence on MTs and the cytoskeleton due to Debye screening. Furthermore, they showed that the torque an MT experiences in a 1 V/cm field is 3 orders of magnitude too low to lead to significant rotation. However, the authors did show that the field non-uniformity in dividing cells could cause substantial DEP forces on tubulin dimers and MTs potentially large enough to disrupt cell division. In addition, they showed that under the influence of TTFields significant ionic currents could develop along MTs that might disrupt cellular function. In the future it would be useful to create complex cellular models by combining the computational models presented here with electromechanical models of mitotic spindle dynamics [68], [69]. These models have already been adapted to address possible mechanisms of the effects of ultra-short electrical and mechanical pulses on dividing cells [70]. It would also be useful to measure the magnitude of TTFields within the cells. This task is challenging. However, a promising technique that can measure local EF in cell cultures has been reported [71]. In the future similar techniques might be applicable to experimentally measure the magnitude of TTFields within cells.

## B. Realistic human head modeling

### 1) Materials & Methods

The creation of realistic human head models is a challenging task, which relies on the segmentation of MRI datasets. Typically, the healthy human head will be divided into tissue types of distinct dielectric properties: the scalp, the skull, the cerebrospinal fluid (CSF), the gray matter (GM) and the white matter (WM). The CSF filled ventricles in the center of the head will also usually be identified. There are many different software packages available to achieve this task in a semi-automated manner.

#### a) Head model creation

The first model created for TTFields simulation studies [72], [73] originated from T1 and proton density weighted MRIs (<http://brainweb.bic.mni.mcgill.ca/brainweb>) of the

Colin27 dataset. The freely available Brainsuite software was used for segmentation [74]. The second model used a dataset of a young healthy female consisting of T1, T2, and diffusion MRI (dMRI) datasets [75]. The open-source package SimNibs v1 [76] which uses Freesurfer [77] for segmenting the cortical tissues and FSL [78] for segmenting the outer tissue layers was adapted for this purpose. Brainsuite was used to create the scalp and skull segmentation of the second model. A recent study [79] has employed a similar approach using the almi5 dataset and the SimNibs v2 software (www.simnibs.org). These models relied on datasets of healthy persons, thus the presence of a tumor was modeled by incorporating virtual lesions consisting of two concentric spheres; the inner sphere represented necrosis surrounded by an enhancing tumor [73], [75], [79]. In Korshoej et al. (2017), 24 tumors were systematically introduced at different positions relative to the active transducer-arrays [79]. In Wenger et al, 2016, three more tumor locations were tested, and also more complex shaped, bigger, more realistic dimensions were assumed [39].

The first model of a patient with recurrent GBM treated with TTFields therapy was created by segmenting structural images with ScanIP, a commercial software [80], [81]. More recently, head models of a patient with GBM and a patient with anaplastic astrocytoma were created using T1, T2 and dMRI datasets [82] (Fig.6). To create these models T1 and T2 data were initially processed using the *mri2mesh* algorithm in SimNibs v2 (www.simnibs.org) to produce a preliminary volume mesh. Subsequently, the surface mesh structures and binary tissue masks produced by the algorithm were edited manually using custom code based on meshfix [83], FSL and Freesurfer algorithms. This was done in order to accurately reproduce the patient's anatomy, particularly in the tumor region and its immediate surroundings.

Fig. 6. Example of patient specific head model based on MRI data. The figure shows an axial T2 MRI image (left) obtained from a 23 year-old female patient with deeply seated anaplastic astrocytoma. The three rightmost panels show the head model and tissue segmentation, which was created from the MRI data (T1 and T2) from the same patient. Electrode positioning is evident from the surface reconstruction and electrodes are paired orange/white (LR) and gray/blue (AP).

Following segmentation, the transducer arrays have to be modeled. The studies by Wenger et al. used the 3-matic package of the Mimics v.14 software (www.materialise.com) for this task. The transducers were modeled as 1 mm high cylinders with a radius of 9 mm and the gel layer was represented by cylinders (0.5-2 mm height) of 10 mm radius. For head models created by Korshoej et al. this step was performed automatically with a custom-written Matlab code (www.mathworks.com). In order to complete the model for FE calculation, the final volume mesh has to be created. For models of Wenger et al., this step was performed with Mimics, while open-source tools in SimNibs, Gmsh [84] and meshfix [83] were employed for the patient models.

#### b) Finite element calculation of the electric field distribution

In order to solve the Laplace equation, the virtual tumor studies used the *Electric Currents* physics of the AC/DC package of Comsol (www.comsol.com). Because of the complexity of the model, the solver had to be chosen carefully to obtain convergence (GMRES with SOR preconditioner). For models by Korshoej et al, FE calculations were performed with SimNibs using GetDP with an implemented Galerkin method [85] and residuals for the conjugate gradient solver required to be  $<10^{-9}$ .

To simulate delivery of TTFields to the models, suitable BCs have to be applied. Typically, continuity of the normal component of the current density at all interior boundaries and electric insulation at the external boundaries are considered. In both the virtual tumor models and the patient based models, the external bases of the active transducer arrays were assigned floating potential BCs that set the potential at that boundary so that the integral of the normal component of the current density was 900 mA per transducer array, summing up to 1800 mA peak-to-peak for an active pair of transducer arrays.

To complete the model, the dielectric properties of the different tissue types have to be defined. Isotropic values of electrical conductivity and relative permittivity of different tissue types are listed in the corresponding articles [73], [75], [82]. Studies of related techniques showed that incorporating the anisotropic nature of electric conductivity within the WM significantly affects results [86]–[89]. This anisotropy can be captured by processing diffusion tensor imaging (DTI) data which estimates the diffusion tensor for each voxel, [90], [91]. For the second virtual tumor model, the raw DTI images were corrected and registered with the FSL diffusion toolbox [92] in order to calculate the principal directions (eigenvectors), principal diffusivities (eigenvalues), and the fractional anisotropy. There exist several ways for the subsequent estimation of the conductivity tensor, as described in detail elsewhere [93].

In models by Wenger et al., the direct mapping (dM) method that assumes a linear relationship between the eigenvalues of the diffusion and conductivity tensors was applied [94], i.e.  $\sigma_v = s \cdot d_v$ , where  $\sigma_v$  and  $d_v$  are the  $v$ -th eigenvalues of the conductivity and the diffusion tensors

respectively. Instead of the initially proposed empirical scaling factor  $s$  [94] which is not generally valid, an adapted  $s$  was considered [95]. Additionally, an adapted volume normalized (vN) mapping method was used, which locally matches the geometric mean of the conductivity tensor's eigenvalues in each voxel to the corresponding isotropic conductivity value (either WM or GM) [96]. In order to incorporate tissue anisotropy into the computational models, the conductivity tensor of each voxel was imported into Comsol for FE computation.

For the patient head models, dMRI processing and conductivity estimation with the DM approach was performed using the *dwi2cond* algorithm in SimNibs. The scaling factor was obtained by fitting only the non-pathological regions of the GM and WM tissues of the contralateral hemisphere to standardized values, because the technique remains to be firmly validated for tumor tissue. Values in the tumor tissue were obtained by extrapolation using the obtained fit. Figure 7A shows a conductivity map obtained from dMRI data from a patient with left frontoparietal GBM alongside the corresponding probability density functions (Fig.7C) of the conductivity values. The mean conductivity value in the tumor region was 0.245 S/m and the interquartile range was 0.077 S/m. Thus the estimated conductivity of the tumor was in the same range as previously reported for gliomas *in vivo* [97]–[99] and agreed well with the conductivity values used in the virtual tumor models. Figure 7 also demonstrates the considerable anisotropy (high fractional anisotropy) in the WM tissue, which has been shown to impact the distribution of the estimated field considerably [75]. It is also evident that

the tumor region is characterized by considerable topographical variability in both conductivity and fractional anisotropy, which highlights the importance of individualized head modeling and conductivity estimation. After conductivity estimation, the resulting anisotropic conductivity tensors were imported directly into SimNibs for FE calculations.

For the virtual models by Korshoej et al., a similar approach was adopted to produce a conductivity tensor for WM and GM using *dwi2cond* algorithm. Isotropic conductivities similar to Wenger et al. were used for the remaining tissues, including the tumor and necrosis.

## 2) Results

The simulation-based studies show that TTFields distribution within the brain is heterogeneous [72], [73], [79], [100] and influenced by the complex tissue interfaces, and especially the differences in dielectric properties of the different tissues. The highest field intensities are found in the scalp and skull close to the active transducer arrays. Although the field in the brain tissue on average decreases with increasing distance from the transducers, field strengths are not necessarily higher for tumors close to the active arrays. This is mainly due to shunting of current through surrounding less resistive CSF pathways during LR array activation [79]. Deeper regions with higher field intensities (hot spots) were also observed (Fig.8), caused by the fact that at a tissue interface the field increases in the lower conductivity medium and decreases in the tissue with higher conductivity. This behavior has also been reported in other non-invasive brain stimulation techniques [101]. In addition, the CSF creates low-resistance pathways causing currents to flow through the sulci, ventricles and resection cavities towards deeper regions, which in turn creates local field “hot spots” in deeply seated tumors embedded in WM, as well as in tumors located close to the sulcal fundi and near resection borders [79]. Higher EF intensities were found for the LR array and the field distribution appears to be more uniform in the AP setting. Nonetheless, the average EF intensities in the brain was estimated to be very similar in the two settings,  $|E_{brain}^{LR}| = 1.18$

V/cm and  $|E_{brain}^{AP}| = 1.14$  V/cm [75]. The AP array configuration delivered higher field intensities to superficial tumors, while the LR configuration delivered higher intensities to deeper tumors [79].

Within the tumor, low field values were found in the necrotic core and higher values with a non-uniform distribution were found in the tumor and peritumoral border zone [73], [79]. Again the directional effects, explained above, were responsible for hotspots created in the tumor, which were far more pronounced in the LR setting for the first tumor location tested [75]. The average EF intensities in the enhancing tumor part depended significantly on the tumor location and ranged between  $|E_{shell}^{LR}| \approx 1.20 - 1.65$  V/cm and

$|E_{shell}^{AP}| \approx 0.75 - 1.40$  V/cm [75], [79].

Another aim of the modeling studies was to clarify to what extent the EF distribution depends on assumptions about the

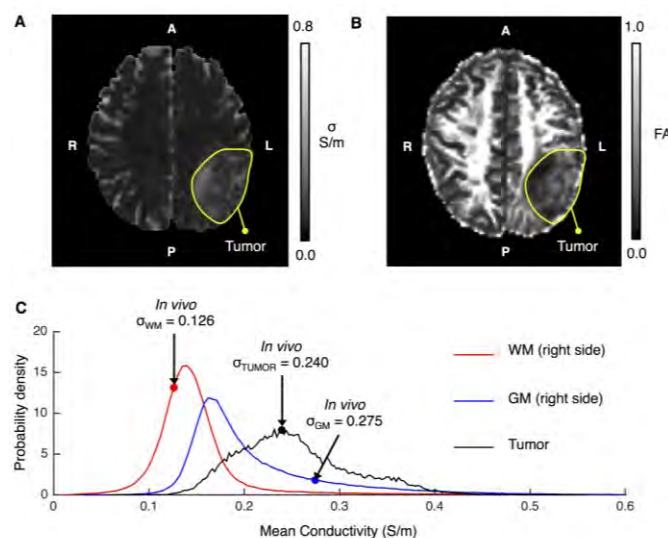

Fig. 7. Conductivity maps and estimation for patient based and virtual tumor models. (A) Axial section of dMRI based conductivity map obtained using SimNibs. The map was created using direct linear mapping based on the right GM and WM tissue and then extrapolating the obtained scale factor to obtain a generalized conductivity map covering the whole brain and tumor. (B) shows the corresponding probability density functions of the conductivity estimates and (C) the fractional anisotropy distribution of the conductivity tensors. As evident from the figures, both distributions in (A) and (B) cover a wide range of values with considerable topographical variability, particularly in the tumor region, which illustrates the potential importance of utilizing patient specific estimates. It is also notable, that the conductivity range and mean values correspond well to *in vivo* estimates.

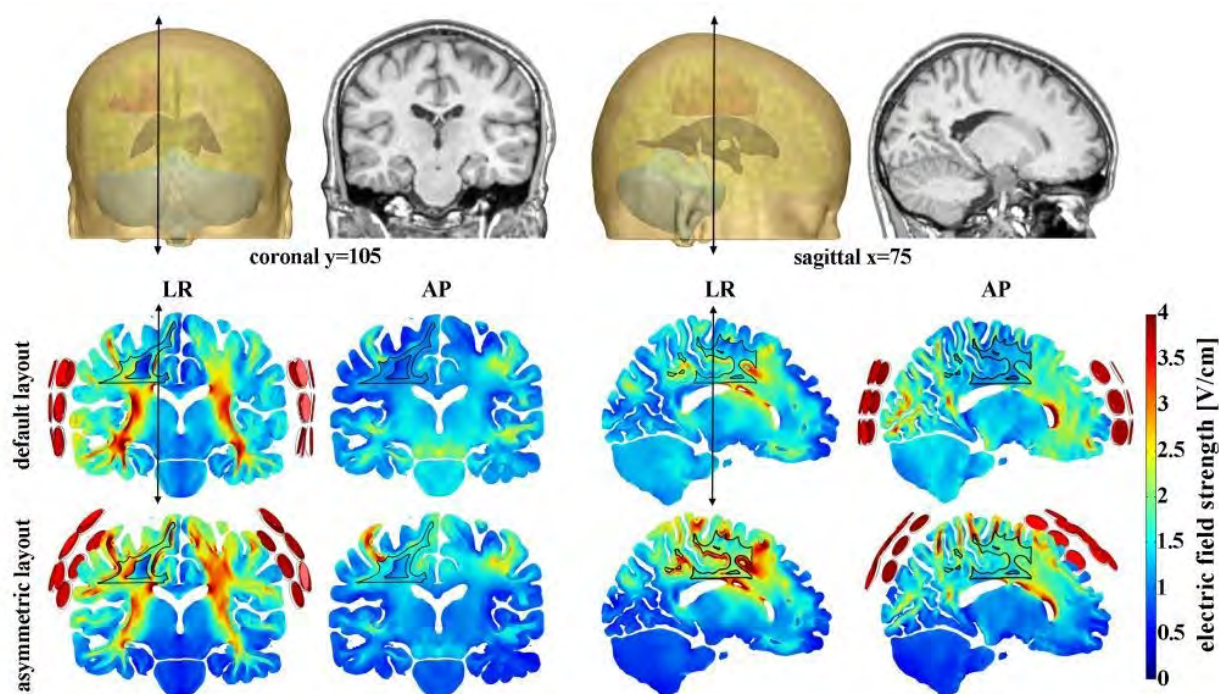

Fig. 8. The distribution of the EF's intensity (V/cm) is presented in two axial slices through a virtual tumor located frontal in the left hemisphere (contour shown in the left hemisphere, anteriorly). Default (2<sup>nd</sup> row) and patient-specific adapted layouts (3<sup>rd</sup> row) are presented for LR and AP setups of the Optune<sup>TM</sup> device. Corresponding anatomical slices and their position in the head model are presented at the top. Reproduced from [38].

dielectric properties of the tissues, and the extent to which tissue anisotropy influences the field distribution [75], [100]. For the second virtual tumor head model, representation of the conductivity tensor using both the dM and the vN methods (section 2.2.1) yielded field distributions that were similar to the field distribution in the isotropic model. The calculated average EF intensities in the brain and tumor showed only minor differences between isotropic and anisotropic models. However, tumor locations in highly anisotropic areas of the WM [79] and possibly also the tumor's intrinsic anisotropy of conductivity can influence the field intensity at the diseased site. Indeed, the field distributions in the patient based models, suggest that the choice of conductivity assignment plays a significant role in determining the field distribution in the regions of pathology. Particularly, the median field intensity is approximately 0.20 V/cm lower in the peritumoral border zone for the patient shown in Fig.7 when the dM anisotropic conductivity tensor is used compared to isotropic scalar conductivity assignment. In WM, GM, and tumor tissue no significant differences in the central tendencies of the field estimates were observed although the choice of conductivity model did affect the topographical distribution of the field in all tissues. Specifically the interquartile range of the paired difference in field estimates for all elements was  $> 0.40$  V/cm for all tissues. The fact that the peritumoral region is more sensitive to the chosen conductivity model, likely indicates that standardized conductivity values for GM and WM do not accurately represent the tissue properties in this region due to the presence of edema and tumor infiltration.

Furthermore, a sensitivity analysis has been carried out to determine how uncertainties in the dielectric properties of

tissues affect the EF in the tumor [75], [100]. Variations of permittivity values by up to 2-fold in all of the head tissues lead to changes in the average field intensity of less than 2% [75]. This is due to the fact, that for TTFields settings the current is mainly resistive as opposed to capacitive, i.e.  $\sigma \gg \omega \epsilon_0 \epsilon_r$  [102]. Furthermore, this result validates the approach of considering a static problem by neglecting the permittivity, as it was done in the patient studies using SimNibs. However, significant differences in the induced EF intensities have been observed when conductivity values of both pathological and healthy tissues are varied by up to 2.5-fold [75]. The percentage difference between the highest and the lowest average field intensity in the brain changes up to 42%. Within the tumor the differences in field intensities can be as large as 68%. The tissues whose conductivity has the greatest effect on the average EF in the tumor are the tumor itself, the skull, and the scalp [75].

The influence of tumor composition on the field intensity was also investigated [79], [100], [103]. The virtual cystic tumors discussed above (with a necrotic core) were replaced with a solid enhancing tumor mass [79], [103]. Although the average field intensity in the active part of the tumor is similar in both cases, the EF distribution is relatively uniform in the solid tumor, but shows hot spots and less exposed areas within the active region, when a necrotic core is introduced.

A consecutive study investigated the influence of tumor size, shape and position on EF intensity [39]. A virtual tumor with the same shape and size as the tumor discussed above was placed at different location within the brain. Two additional tumors with irregular shape and larger sizes were placed in the left hemisphere (Fig.8). The computational

results show that tumor shape and size, up to 26.6 cm<sup>3</sup> total volume, did not have a noticeable impact on the average EF intensity in the tumor, owing primarily to the large size of the individual arrays. Simulations revealed that the induced average EF intensity value remained above 1 V/cm for all tumors irrespective of the direction from which TTFields was delivered. However, visual examination of the field distribution suggested that the default position of the arrays tested in these simulations might not optimal field intensities to all tumors. Tumors in the anterior region are not well covered by the default LR array placed above the ears, although their proximity to the frontal AP patch has been shown to induce high field intensities (Fig.8). For superficial tumors, the patches are too low to induce optimal field delivery. The study therefore investigated how adapting the transducer arrays positions to specific tumor location influenced field intensity. Indeed, for all tumor locations, moving the patches closer to the region containing the tumor increased the induced average EF intensity in the tumor (Fig.8). Details can be found in [39].

Since there exist models of two individuals with the same virtual tumor in terms of size, position, and properties, conclusions about patient variability can be drawn [75], [104]. The second model generally showed higher EF intensities, with average values 20% and 50% higher for LR and AP configurations respectively. The two heads have different shape and size (the first model head is bigger), and an exploratory analysis showed that the median thickness of the scalp and skull are 94% and 75% smaller respectively in the second model. Thickening the skull in the second model and increasing the head size of the second model [39] brings the average EF intensities in the tumor closer to the values observed in the first model. These studies illustrate the large extent to which individual head shape and size, and the geometry and thickness of the tissue compartments [100] influence TTFields distribution within the head.

### 3) Discussion and Future Directions

Currently there are no non-invasive methods to image the induced TTFields in the head during therapy. Only one intracranial measurement of TTFields intensity has been performed on a human subject. This measurement showed that TTFields intensity within the center of the brain ranges between 1–2 V/cm, and is within 10% of the predicted values [6]. The development of realistic human head models has allowed detailed description of EF distribution in the head following Optune treatment. This is an important step towards understanding the basic features of the induced field, which are not entirely intuitive. The induced field is highly non-uniform and depends on the complex tissue interfaces and their dielectric property distributions. This results in regions of high field intensity not only close to active transducers but also in deep areas of the brain.

Realistic computational models have also enabled quantification of the EF intensity delivered to the tumor, and show that TTFields intensity in large regions of tumors exceeds the therapeutic threshold of 1 V/cm, irrespective of

head geometry, tumor location and size, and array configuration. The field estimates are influenced by model uncertainties, particularly by uncertainties of the chosen ohmic tissue conductivities. The conductivity is frequency dependent [105] and the intermediate frequency range is least studied and experimental results often cover the low-frequency or higher frequency regimes. In addition, the values reported in the literature possess a substantial spread. Given that the computational study employing a virtual tumor model demonstrated a clear sensitivity of the calculated fields on the chosen tissue conductivities, specific measurements would be highly desirable and would certainly provide an opportunity to improve the accuracy and precision of the model results. This not only relates to the conductivity of the main tissues (skin, skull, CSF, brain gray and white matter), but also to the conductivity of the tumor tissue, which might possess a wide inter-individual spread due to differences in tumor type and “stage of development”. The latter notion is supported by the documented inter-individual variation in apparent diffusion coefficient (ADC) in the tumor region and also the established correlation between ADC values and glioma grade [106].

Virtual tumor models have the advantage of being versatile and able to simulate virtually every situation in terms of tumor location, shape and size, as well as head shape and size. The influence of each of these parameters can be studied systematically. One study investigated adapting transducer arrays to specific tumor locations, to clarify how beneficial the treatment planning with NovoTAL™ might be. The modeling results confirmed that the EF intensities can be significantly increased when a patient-specific array layout is used. However, only one subject was tested with virtual tumors and another study already predicted differences in the induced field for two different persons. Computational modeling has the potential to identify the properties of the head that result in these differences. One small study started to investigate the effect of different head size and thicknesses of outer tissue layers. It would be possible to deform the virtual tumor model into different shapes and scale tissue to produce a more individual model [107]. However, these techniques might underestimate altered anatomy due to disease (edema, midline shifts, etc.) in a real patient.

Thus, patient head models, which are created by directly segmenting patient MRI datasets, are a highly important addition to the computational simulation of TTFields application in clinical settings. Such patient specific models have recently been applied in a study aiming to investigate the potential benefit of combining TTFields with surgical craniectomy [82]. A clinical phase I trial testing the safety and feasibility of this procedure was recently launched (NCT02893137). This example highlights how computational modeling can facilitate translational research.

Despite the considerable potential of patient specific models, further investigations are required to firmly validate the technique. An important aspect will be the further validation of the dMRI approach for conductivity estimation on a larger number of patients, potentially by correlating

dMRI estimates of conductivity to stereotactic *in vivo* measurements from the same patient [82].

Furthermore, ongoing studies by the authors aim to characterize the importance of tumor locations and morphological characteristics such as size, shape, mean conductivity distribution and fractional conductivity anisotropy on the distribution of the induced field [82]. Such an investigation would be an important addition to the studies performed with the virtual head models, because of the valuable insight on the tumor's heterogeneous environment and its influence on the induced field. A recent study presented a first attempt to create simpler head models that can provide accurate results for calculating the EF distribution for the application of TTFields [108]. However, future feasibility studies based on a number of datasets should address the performance of this simplified model.

Currently, the frameworks available for creating patient-specific models are cumbersome and time-consuming [82]. This is primarily because algorithms for automatic tumor segmentation are inaccurate. Hence considerable manual intervention is required to obtain models that accurately represent patients. For successful clinical implementation of future modeling technologies the time required to create models and run simulation should be minimized. Thus, an effort should be made to improve segmentation and model creation algorithms to obtain the goal of rapid patient-specific modelling; a parallel investigation into how much complexity is needed in a model to produce reliable predictions of the EF distribution should also be performed.

Clinical investigations have shown a favorable safety profile of TTFields and Optune in particular. Already the virtual head models were used to evaluate SAR values in the scalp, skull and brain tissues [73], [75]. In the patient head models, peak SAR values were increased by craniectomy but still within the range of median SAR values previously reported [82]. It was concluded that the treatment would not impose additional risk of overheating or damage of healthy tissue [82]. Apart from investigating induced SAR values, these modeling studies could also be adapted to specifically study the heat distribution in the head from Optune treatment.

There are many avenues through which computational head models could be used to address clinical questions. The tools described here could be employed to conduct a retrospective outcome analysis in which patient-specific models are created and the connection between disease progression and field distribution could be investigated. Computational models combined with a deep understanding on how field distribution influences disease progression could then be used for adaptive treatment planning. Realistic head models of a patient could be created periodically during the course of treatment, reflecting dynamic changes in tumor morphology and tissue properties [82]. These models could be combined with simulations and an understanding of field intensity influences disease progression to optimize TTFields delivery in a dynamic manner throughout the course of treatment.

### III. SUMMARY AND CONCLUSION

In this review, we showed how modelling at different scales can be employed to study TTFields application. At a cellular scale, simulation studies can be used to strengthen physical understanding and basic knowledge of cell-EF interaction. With the creation of realistic human head model it is possible to investigate TTFields in clinical practice by analyzing induced EF distributions in the patient's brain and tumor during Optune<sup>TM</sup> treatment. Important insights can be obtained from these calculations, such as retrospective analysis of treatment outcome as well as prospective personalized treatment planning. In conclusion, TTFields is yet another application, where computational modeling acts as an integral part for further development and efficacy improvement of a therapy. Clinical and engineering communities will greatly benefit by collaborating and drawing from common resources and knowledge.

# Understanding and Treating Glioblastoma

Wolfgang Wick, MD<sup>a,b,\*</sup>, Michael Platten, MD<sup>c,d</sup>

## KEYWORDS

• Glioblastoma • MGMT • Repositioning of drugs • Precision medicine • Biomarker  
• Radiomics • Treatment resistance • Immunotherapy

## KEY POINTS

- Molecular biomarkers are entering diagnostics in neurooncology; current efforts aim at developing biomarkers-based treatment concepts.
- Understanding and overcoming resistance at multiple levels is the key challenge in glioblastoma; reviewing the failure of past concept-driven approaches such as antiangiogenic therapies or trials of unselected populations is necessary.
- The failure of recent immunotherapy trials should provide lessons for future development.
- Despite limited options to molecularly stratify glioblastoma into different age groups, patient functional status and age are key factors to consider for treatment decisions.

## INTRODUCTION

The natural disease course in glioblastoma (GB) is invariably grim. A clinical event (eg, a seizure) or a cerebral image incidentally triggers clinical workup, commonly resulting in a maximal safe surgery. Diagnosis is made by careful neuropathological assessment of the tissue, including immunohistochemistry and selected molecular tests. Adjuvant treatments include radiotherapy (RT) to an area of the brain defined by the contrast-enhancing volume plus a safety margin, as well as alkylating chemotherapy with temozolomide (TMZ).<sup>1</sup> Variation at this stage is limited and may include modification of RT (and sometimes chemotherapy) according to age,<sup>2</sup> and the intensification or omission of alkylating chemotherapy according to the methylation status of the promoter region of the *O<sup>6</sup>-methylguanine DNA-methyltransferase* (MGMT) gene<sup>1,3,4</sup> and

potentially point mutations in the promoter of the *telomerase reverse transcriptase* (*TERT*) gene, resulting in increased telomerase expression.<sup>5</sup>

Currently available GB treatments are not curative but there are subgroups of patients who derive greater benefit from current treatments, radiation, and alkylating chemotherapy, as well as experimental targeted or immune therapies. Features hampering treatment efficacy across many cancers are prominently present in GB: rapid and infiltrative growth, most likely imitating features of normal brain development<sup>6</sup>; clonal heterogeneity with a component of primitive (or stem-like) features, varying over time with treatment selection<sup>7</sup>; and pathologic angiogenesis, resulting in a hypoxic and immunosuppressive microenvironment.<sup>8</sup>

Whereas the concept of molecular subclassification defined by gene expression and DNA methylation has been spearheaded<sup>9</sup> and further refined<sup>10,11</sup> in GB, the immediate clinical impact on the diagnostic classification,<sup>12</sup> treatment, or even trial development has remained limited. Consequently, trials to date do not use epigenetic or genetic criteria to biologically subdivide GB. *MGMT* promoter hypermethylation (despite its relevance as a predictive marker for response to alkylating chemotherapy) has almost no impact on clinical decision-making, except perhaps in elderly patients.

Understanding of molecular characteristics and cell intrinsic mechanisms of GB pathogenesis has evolved in the last decade.<sup>6,9–11,13</sup> The updated 2016 World Health Organization classification of central nervous system tumors<sup>12</sup> integrates genotypic and phenotypic parameters to GB diagnostics, notably the presence or absence of *isocitrate dehydrogenase* (*IDH*) mutations. These and other mutated drivers in GB are putative targets for treatment. Recent studies in colon cancer revealed that subjects with mismatch repair deficiency (dMMR) respond better to anti-programmed death (PD)-1 therapy.<sup>14</sup> Additional studies indicate that other solid tumors with MMR deficiency, including GB, are sensitive to anti-PD1 therapy.<sup>15,16</sup> There is increasing effort to integrate molecularly informed diagnoses into therapy decision-making.<sup>17–19</sup> Although precision medicine in cancer proposes that genomic characterization of tumors can inform personalized targeted therapies, this proposition is complicated in GB by spatial and temporal heterogeneity.<sup>20</sup>

In parallel with the generation of increasingly complex molecular models for ex vivo data analysis, advanced MRI and data analysis (eg, radiomics) are being developed to decipher information about tumors noninvasively.<sup>21</sup>

Despite all efforts and successes in other solid tumors and the enormous power of basic science in neurooncology, a lack of stringent integration of the existing knowledge into clinical (research) practices has left GB lagging behind the current evolution of modern oncology. The focus to date on traditional all-comers trials, as well as the dearth of widely accepted molecular tests and subsequent enrichment strategies, are important obstacles. An example of concepts in which selection might have made a difference includes the antiangiogenic studies with bevacizumab. Despite the post hoc development of a predictive RNA expression signature favoring bevacizumab treatment in proneural subtypes,<sup>22</sup> the proof-of-concept study has still not been planned. Other examples of putative biomarkers that can be used for subject selection include methylation levels for CpG2 in the region of the *CD95 ligand* (*CD95L*) gene promoter as a predictive biomarker for the CD95L inhibitory recombinant protein asunercept combined with reirradiation in recurrent GB<sup>23</sup> and mechanistic target of rapamycin (mTOR) Ser2448 phosphorylation as a predictive biomarker for the mTOR inhibitor temsirolimus in newly diagnosed GB.<sup>24</sup>

In GB, which harms patients by locally destructive brain growth as opposed to systemic metastases, immunosuppression has been extensively studied. Multiple pathways are proposed to mediate GB-associated immunosuppression.

Among these are transforming growth factor beta (TGF- $\beta$ ) and CD95 signaling; checkpoint receptors, such as cytotoxic T cell antigen-4 and PD-1; and intracellular signaling involving tryptophan metabolism and enzymes, such as indoleamine-2,3-dioxygenase (IDO) or tryptophan-2,3-dioxygenase (TDO).<sup>25,26</sup> Although trials to inhibit TGF- $\beta$  have largely failed to date,<sup>27</sup> the success story of checkpoint inhibition in melanoma and other cancers awaits confirmation in GB. Again, current clinical trial data do not support the efficacy of checkpoint inhibitor in all-comers, unselected population trials in GB. However, there is already a path for GB patients harboring microsatellite instability-high (MSI-H) or dMMR to be treated with the PD-1 inhibitor pembrolizumab. The US Food and Drug Administration granted accelerated approval to pembrolizumab for adult and pediatric patients with unresectable or metastatic MSI-H or dMMR solid tumors who have progressed following prior treatment and who have no satisfactory alternative treatment options.

Vaccine-based immunotherapies vary in design with respect to target selection and vaccine generation. Targets selected for vaccine development in GB include monogenic approaches, such as epidermal growth factor receptor variant III (EGFRvIII),<sup>28</sup> IDH1 (R132H),<sup>29,30</sup> or H3.3K27 M<sup>31</sup>; predefined multiepitope approaches, such as in IMA950<sup>32</sup>; profiling-based selection of a limited number of targets (eg, glioma actively personalized vaccine [GAPVAC]); unbiased approaches with undefined tumor-derived peptides (eg, HSPPC-96); or whole tumor cell lysates (eg, DCVax). To date, well-conducted phase 3 randomized controlled trials, such as ACT IV (examining the addition of rindopepimut, a vaccine against epidermal growth factor receptor variant III (EGFRvIII), to standard of care in newly diagnosed EGFRvIII mutant GB) have not demonstrated efficacy for glioma vaccines.<sup>28,33</sup> The failures in these trials should not distract investigators from developing further vaccine trials in glioma subjects. Instead, important questions, such as target and subject selection, vaccine vehicle, and combination strategies should be addressed upfront in any vaccine trial. This will require innovative, well-designed clinical trials, including assessment of posttreatment tumor tissue. Only then can the magnitude and nature of the intratumoral immune response in response to treatment, and the mechanisms of response and resistance in correlation to peripheral immune biomarkers, imaging parameters, and outcome, be understood.

## CURRENT CHALLENGES AND OPPORTUNITIES

Several groups have proposed that GB is a widespread disease of the brain and not a focal malignant growth. The efficacy of currently available therapies is likely limited by GB's propensity for rapid and infiltrative growth. GB cells interconnect via a functional tumor cell network composed of thin and very long membrane tubes called tumor microtubes (TMs),<sup>6</sup> most likely imitating features of brain development. Growth associated protein 43 (Gap43) and tweety-homolog 1 (Tthy1), 2 already known molecular drivers of TM formation in GB, also play an important role in neurodevelopment.<sup>34</sup> Given the prominent role of TMs, discovering and exploring functional candidates to target and disrupt the network will be a challenge but also an opportunity for the future.

### *Improving Standard Therapies*

Maximal safe surgery has shown to be beneficial for subjects in several trials and the extent of surgical resection is often among the most important prognostic factors in trials. Despite the conceptual challenges of further improving a local treatment, surgery is key for tissue sampling from different areas of the tumor, thus allowing spatial annotation of samples to model heterogeneity in GB. Therefore, it seems plausible to

adapt and refine surgical techniques with the addition of fluorescence to dissect GB cell compartments with lower or higher oxygen levels and differential stem cell content,<sup>35</sup> or with intraoperative MRI to optimize macroscopic tumor removal.<sup>36</sup>

RT to a limited part of the brain (despite the conceptual shortcomings of focal treatments) can likewise further improve radiation target definition (ie, using metabolic imaging<sup>37</sup>) and avoid neurotoxicity (eg, with protons by reducing nontarget tissue dose), although the overall clinical benefit of dosimetric advantages in GB patients remains to be determined.<sup>38</sup> Also, the claimed differential DNA repair pathway choice following proton versus photon radiation<sup>39</sup> needs clinical substantiation.

Tumor-treating fields (TTFields) use alternating electrical fields to inhibit mitoses via disruption of the spindle apparatus.<sup>40</sup> In a randomized trial, the addition of TTFields to standard RT and TMZ in newly diagnosed GB extended overall survival (OS) (hazard ratio [HR] 0.64, 99.4% CI 0.42–0.98,  $P = .004$ ).<sup>40</sup> Whether the magnitude of OS benefit justifies the individual burden and the societal cost is yet to be determined. The long-term relevance of these fields will be determined by whether they are routinely integrated into daily practice and the success (or not) of other concepts (see later discussion).

Other recent data regarding improving the standard of care treatment concern the intensity or duration of TMZ. There is no clear benefit to extending TMZ maintenance therapy beyond 6 cycles.<sup>41</sup> In contrast, results from the CeTeG/NOA-09 phase III trial in subjects with newly diagnosed hypermethylated *MGMT* GB suggest an OS benefit for the combination of RT with lomustine (CCNU) and TMZ<sup>4</sup> (see later discussion).

## UPDATE ON THE ELDERLY

According to the Central Brain Tumor Registry of the United States (CBTRUS) statistical report, which comprises data on subjects with malignant primary central nervous system tumors diagnosed between 2006 and 2010, the median age at GB diagnosis is 64 years.<sup>42</sup> This means that almost half of all patients diagnosed in the United States with GB are elderly (age  $\geq 65$ –70 years) as defined in GB clinical trials. Treatment principles should be the same for both elderly and young GB patients, with a focus on maximizing benefit and minimizing risk from every intervention. However, a more detailed assessment of the risks and benefits are needed for elderly patients because the benefit is generally not as great in elderly compared with younger patients. Based on a variety of trials in elderly subjects, options could include standard RT and alkylating chemotherapy as per standard of care in younger patients, hypofractionated RT and TMZ, RT alone (either standard or hypofractionated schemes), or TMZ alone (Table 1).

In patients with good Karnofsky Performance Status (KPS) greater than or equal to 70, aged 65 to 70 years, and with hypermethylated *MGMT* promoter, combined hypofractionated RT and TMZ is recommended based on randomized data from CCTG CE.6/EORTC 26062 (Canadian Clinical Trial Group (CCTG) CE.6/European Organization for Research and Treatment of Cancer (EORTC) 26062).<sup>43</sup> As long as randomized data on TMZ monotherapy (or the previous CETEG regimen) versus chemoradiation are lacking, TMZ alone seems reasonable in *MGMT*-methylated elderly patients when poor KPS or patient preference suggests that combined treatment may be too toxic.

In patients with KPS 70 years and older, and age 65 to 70 years and older, unmethylated *MGMT*, hypofractionated RT and TMZ is also recommended, recognizing that the benefit of adding TMZ is less in the unmethylated *MGMT* population.<sup>43</sup> Similarly, RT alone seems reasonable in unmethylated *MGMT* elderly patients when poor KPS or patient preference suggests that combined treatment may be too toxic. Further research on patients with unmethylated *MGMT* is needed.

**Table 1**  
**Compilation of therapy options and recommendations for patients with glioblastoma in different age groups according to Karnofsky Performance Status<sup>a</sup>**

MGMT	Age (y)	Karnofsky Performance Status	First Choice	Second Choice
Hypermethylated or undetermined	>70	50–70	TMZ	Hypofractionated (Hypo) RT or TMZ
	>70	>70	Hypo RT or TMZ	TMZ
	<70	<70	Hypo RT or TMZ	(TMZ)
	<70	>70	RT or TMZ	—
Unmethylated	>70	50–70	Hypo RT	(Hypo RT or TMZ)
	>70	>70	Hypo RT	Hypo RT or TMZ
	<70	<70	Hypo RT	Hypo RT or TMZ
	<70	>70	RT or trial	RT or (TMZ)

<sup>a</sup> Regimens are depicted as hypofractionated RT-TMZ<sup>43</sup> or RT-TMZ.<sup>68</sup>

## RECENT TRIALS

CCTG CE.6/EORTC 26062 (the aforementioned randomized phase III trial in elderly subjects comparing hypofractionated RT alone or in combination with TMZ) clearly has an impact on practice and provides evidence for shorter chemoradiation schedules for select subjects and advocates for TMZ use in these subjects, although the authors of this review question the utility of testing for *MGMT* in subjects with good KPS because combined chemoradiation is recommended regardless of *MGMT*. In contrast, other recent trials also aimed to change practice but largely failed. Lessons may or may not be gleaned from these negative trials.

ACT IV was a randomized, double-blind, phase III trial, which recruited adult subjects with newly diagnosed GB with centrally assessed EGFRvIII expression from 165 hospitals in 22 countries. Subjects were required to have undergone a maximal surgical resection and completion of standard RT and concurrent TMZ without progression. During TMZ maintenance therapy (6–12 cycles), subjects were randomized the EGFRvIII vaccine rindopepimut (500 µg admixed with 150 µg GM-CSF) or control (100 µg keyhole limpet hemocyanin), administered via monthly intradermal injection until progression or intolerance. The addition of rindopepimut failed to improve OS with a median OS of 20.1 months (95% CI 18.5–22.1) in the rindopepimut group versus 20.0 (95% CI 18.1–21.9) months in the control group resulting to a HR of 1.01 (95% CI 0.79–1.30,  $P = .93$ ).<sup>28</sup> Because ACT IV followed a promising small, uncontrolled trial of rindopepimut, the lessons learned should include an even higher skepticism concerning small, uncontrolled trial data.<sup>33</sup> This earlier trial also demonstrated an absence of EGFRvIII in rindopepimut-treated tumor specimens and was considered a proof of benefit from rindopepimut.<sup>44,45</sup> However, analysis of posttreatment tumor specimens from ACT IV reveal that a variable percentage of subjects lose EGFRvIII (based on RT-PCR) regardless of treatment arm, raising suspicion of the limited relevance of the EGFRvIII mutation in general. Such information could have been detected earlier with a control in the earlier study.<sup>28,46</sup> Interestingly, contrasting data from 106 subjects demonstrated that EGFRvIII status was unchanged at recurrence in 35 of 40 subjects with EGFR-amplified primary tumors (87.5%).<sup>47</sup> Four subjects lost and 1 subject gained EGFRvIII positivity at recurrence.<sup>47</sup> Agreement on methodological discrepancies for defining EGFR amplification and EGFRvIII positivity may solve the issue. Despite this negative phase III trial of EGFRvIII-directed immunotherapy,<sup>28</sup> the target

may still be relevant for precision approaches; for example, with the drug-antibody conjugate composed of the humanized chimeric EGFR-targeted monoclonal antibody ABT-806 conjugated via a stable maleimidocaproyl linker to the tubulin inhibitor, monomethylauristatin.<sup>48</sup>

After the failure of bevacizumab to demonstrate an OS benefit when added to standard of care in the newly diagnosed setting, the Bevacizumab, Lomustine, or Both (BELOB) trial provided a promising survival signal in recurrent GB, which prompted the EORTC 26101 phase II trial to be transformed into a full phase III study. BELOB demonstrated improved OS at 9 and 12 months for combined bevacizumab and lomustine versus either agent alone. Of note, bevacizumab was not accessible in the Netherlands, where the BELOB study was performed, thus restricting crossover to bevacizumab in the control group ( $n = 1$ ).<sup>49</sup> The subsequent randomized, phase III EORTC 26101 compared lomustine with or without bevacizumab. Despite prolonging progression-free survival (PFS) (HR 0.49, 95% CI 0.39–0.61), combined lomustine and bevacizumab treatment does not confer an OS advantage (HR 0.95, 95% CI 0.74–1.21,  $P = .650$ ) compared with treatment with lomustine alone in subjects with progressive GB.<sup>50</sup> In this study, crossover to bevacizumab occurred in 35.5% of subjects in the control arm; whereas 18.7% of subjects in the combination arm continued bevacizumab at progression.

Large-scale clinical trials are currently evaluating the efficacy of immune checkpoint inhibitors, namely nivolumab, in newly diagnosed and recurrent GB. Whereas the trials in newly diagnosed subjects separated according to *MGMT* promoter methylation status are ongoing, results from the study in progressive GB comparing nivolumab and bevacizumab have been reported. This trial randomized 369 subjects at first progression after standard of care to nivolumab 3 mg/kg every 2 weeks ( $n = 184$ ) or bevacizumab 10 mg/kg every 2 weeks ( $n = 185$ ). The most common adverse events leading to discontinuation ( $>2$  subjects in either the nivolumab or bevacizumab arm) were cerebrovascular accident (0% and 2%, respectively) and pulmonary embolism ( $<1\%$  and 2%, respectively). PFS favored bevacizumab (HR = 1.97, 95% CI 1.57–2.48) with median PFS 3.5 months (2.9–4.6) for bevacizumab and 1.5 months (1.5–1.6) for nivolumab. OS was similar in this unselected subject population (HR = 1.04, 95% CI 0.83–1.30,  $P = .76$ ) with median OS 10.0 months (9.0–11.8) for bevacizumab and 9.8 months (8.2–11.8) for nivolumab.<sup>51</sup> CheckMate 498 (nivolumab or TMZ in combination with RT in newly diagnosed subjects with *MGMT*-unmethylated GB) and CheckMate 548 (nivolumab or placebo in combination with RT plus TMZ in newly diagnosed subjects with *MGMT*-methylated or indeterminate GB) are ongoing. These trials also do not enrich for subjects more likely to benefit from the immune intervention.<sup>16</sup>

As previously mentioned, the CETEG trial used *MGMT* promoter hypermethylation to identify subjects most likely to benefit from alkylating chemotherapy. Newly diagnosed GB subjects harboring a hypermethylated *MGMT* promoter were randomized (1:1) to standard chemoradiation with TMZ concurrent and adjuvant for 6 cycles versus experimental therapy with RT and CCNU/TMZ. The experimental chemotherapy was given as 6 42-day courses of CCNU at 100 mg/m<sup>2</sup> on day 1 and TMZ 100 mg/m<sup>2</sup> on days 2 to 6. The first cycle of alkylating chemotherapy was dosed to coincide with days 1 to 6 of RT, replacing continuous concomitant TMZ. The TMZ dose was adapted according to tolerance. The trial randomized 141 subjects (63 TMZ, 66 CCNU/TMZ) with 129 subjects in the modified intention-to-treat (mITT) population of subjects receiving at least 1 dose of study drug. OS was superior in the CCNU/TMZ arm as compared with the TMZ arm ( $P = .049$ ) after stratification for recursive partitioning class and center. In the mITT population, median OS trended toward benefit in the CCNU/TMZ arm at 37.9 months (95% CI 29.2–51.4 months)

compared with 31.4 months (95% CI 27.0–44.8 months) in the TMZ arm (HR 0.60, 95% CI 0.35–1.03,  $P = .064$ ).<sup>4</sup> This trial constitutes an advantage in the group of GB subjects sensitive to alkylating chemotherapy. Due to its limited size, adaption for unevenly distributed risk factors was necessary. Whether a desired confirmatory trial is feasible, given the wide availability of the drugs and the reasonable costs, needs to be discussed.

The sheer number of negative GB trials over the past years despite concepts or compounds that work well in other diseases should trigger appraisal of potential factors contributing to these failures:

- More than in other solid malignancies, residual tumor after surgery may harbor yet unknown properties that limit treatment efficacy. An argument for this is the newly discovered network of TMs.<sup>6</sup>
- There is a failure to conceptually understand that the overarching principle to be tackled is the heterogeneity of the disease<sup>20</sup> and there is a lack of smart, tolerable combination approaches that appropriately tackle this issue.
- Molecular diagnostics, wherever possible, should be used to improve accuracy of patient selection.
- There was failure to decide if standard of care for all GB subjects should include TMZ<sup>1</sup> (and/or TTFIELDS<sup>40</sup>) or if treatment should be better individualized.
- A rush to pivotal, phase III trials driven by the rules of the market and regulatory bodies for approval prevents step-wise understanding, building on controlled early-phase data, as well as prudent use of scientifically sound biomarkers, for determining subsets of patients who benefit.
- Trials at recurrence are largely built on information of the newly diagnosed disease.
- The measures to determine treatment response or resistance are largely MRI-based, which, despite all standardization,<sup>52</sup> may be insufficient compared with liquid biopsies or radiomic integration of data.<sup>21</sup>
- Currently, trials of targeted therapies and immunotherapies in GB are mainly in unselected subject groups.

In the following sections, some of these concepts are discussed.

## PRECISION MEDICINE APPROACHES

Precision neurooncology relies on the existence of biomarkers that predict response and ultimately benefit from a given therapy. The most prominent example for a predictive biomarker in gliomas so far is *MGMT*.<sup>1,3</sup> However, some investigators suggest that predicting response to TMZ is more complex than just *MGMT* methylation status and defining the right subgroups that do not benefit from TMZ may also involve global methylation profiles and *TERT* status.<sup>5</sup>

Examples of putative predictive biomarkers exist. Patients with newly diagnosed GB harboring a proneural subtype based on expression analyses<sup>53</sup> may derive benefit from the addition of VEGF antibody bevacizumab to standard treatment. If independently confirmed, this would make the proneural subtype a predictive lesion for response to bevacizumab.<sup>22</sup> Similarly, lower levels of methylation of the CpG2 in the promoter of the *CD95L* were predictive for an improved OS with the *CD95* inhibitory treatment with asunercept (APG101) in combination with reirradiation compared with reirradiation alone. Interestingly, patients with lower methylation of the promoter treated with reirradiation alone (ie, not treated with the *CD95* inhibitory therapy) did worse.<sup>23</sup> Also, based on retrospective analysis, mTOR Ser2448 phosphorylation is

an interesting putative predictive biomarker for the response to the mTOR inhibitor temsirolimus plus radiation in patients with newly diagnosed GB without *MGMT* promoter methylation.<sup>24</sup> This seems even more important because, without population preselection, mTOR inhibition is not only ineffective but may even confer a survival disadvantage compared with the standard of care. The addition of a different mTOR inhibitor, everolimus, in a recent controlled study did not provide any advantage in an unselected group of subjects with newly diagnosed GB irrespective of *MGMT* status.<sup>54</sup> In some GBs, B-raf proto-oncogene (*BRAF*) mutations may indicate response to *BRAF* inhibitory treatments.<sup>55</sup> Only recently, an association between a reduced capacity of the tumor cells to repair DNA lesions (MMR deficiency) and positive response to immune checkpoint inhibition has been proposed for lung cancer.<sup>14</sup>

Therefore, well-considered allocation of subjects to clinical trials based on the molecular characteristics of the tumor, as well as necessary retrospective validation of potential biomarkers, is essential in a clinical setting. Current concepts prospectively using biomarkers to enrich for potentially benefitting patients are the Individualized Therapy for Relapsed Malignancies in Childhood (INFORM) trial<sup>56</sup> and the Nationale Centrum für Tumorerkrankungen (NCT) Neuro Master Match (N<sup>2</sup>M<sup>2</sup>), a trial of molecularly matched targeted therapies plus RT in subjects with newly diagnosed GB without *MGMT* promoter methylation.<sup>19</sup> The GB Adaptive, Global, Innovative Learning Environment (AGILE) consortium is planning to take a differential approach by reassessing potential biomarkers from an unselected cohort with given therapies first and integrating this information via adaptive processes to enrich while the trial accrues.<sup>57</sup>

Similar concepts are also being developed for the recurrent disease. One example is that subjects with progressive GB undergo resection for extensive biomarker analysis to allow selection of appropriate treatments from a large set of agents.<sup>18</sup> The concept and potential candidate drugs are outlined in [Fig. 1](#).

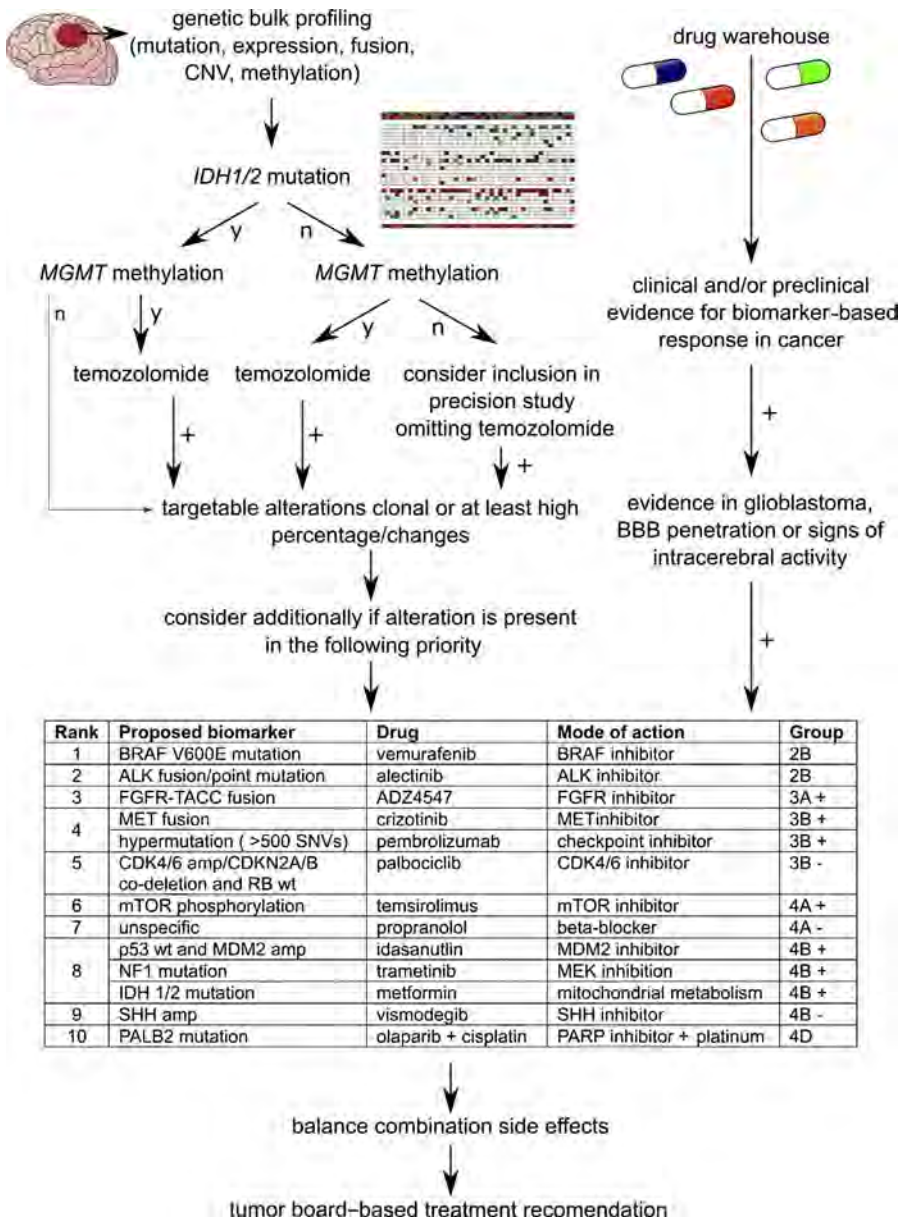

## IMMUNOTHERAPY

Immunotherapy may represent the next big step for patients with GB ([Fig. 2](#)). In addition to the successes in other malignancies, this optimism is fueled by single cases and attractive concepts. Independent of the approach (eg, checkpoint inhibition, targeted vaccine, or adoptive T-cell transfer), the clonal representation of the target antigen and the immunosuppressive microenvironment must be taken into account for clinical development. For instance, EGFRvIII is a subclonal antigen with heterogeneous expression in the tumor tissue, which may, in theory, be subjected to immune evasion. The early founder mutations IDH1R132H<sup>29</sup> and H3.3K27M<sup>31</sup> represent clonal antigens.

Several chimeric antigen receptors (CARs) are in clinical development for GB-targeting tumor antigens, such as interleukin 13 receptor- $\alpha$ 2, EGFRvIII, and human epidermal growth factor receptor 2. A proof-of-concept report in a patient with recurrent, multifocal GB validates a robust antitumor killing capability of CAR T cells in general.<sup>58</sup> In a series of 10 subjects, intravenous delivery of a single dose of autologous T cells redirected to the EGFRvIII mutation by a CAR showed feasibility of manufacturing and intravenous delivery of CAR T-EGFRvIII cells.<sup>59</sup> There was no evidence of a cytokine release syndrome and CAR T-EGFRvIII cells transiently expanded in the peripheral blood.<sup>59</sup>

- Concepts to enhance activity of drugs and prevent development of resistance deserve exploration of strategies against immune inhibitory pathways, potentially

**Fig. 1.** Path toward precision. Paradigmatic work flow from a recurrent GB tissue sample is outlined. ALK, anaplastic lymphoma receptor tyrosine kinase; amp, amplification; BBB, blood-brain barrier; CDK, cyclin-dependent kinase; CDKN 2A/B, cyclin-dependent kinase inhibitor; CNV, copy-number variation; FGFR, fibroblast growth factor receptor; MDM 2, mouse double minute; MEK, mitogen-activated protein kinase; MET, hepatocyte growth factor receptor; n, no; NF1, neurofibromin; PALB 2, partner and localizer of BRCA; poly (ADP-ribose)-polymerase; RB, retinoblastoma; SHH, sonic hedgehog; SNV, small nucleotide variants; TACC, transforming acidic coiled-coil; wt, wild-type; y, yes.

have failed to learn from successes and defeats. Neurosurgical and standard chemoradiation approaches may have reached their boundaries; yet, the most and least benefitting patients, as well as the mechanisms of secondary resistance, are not understood.

Concepts currently explored in radiation oncology focus on target definition and use of alternative radiation qualities. After many years of focusing on targeting angiogenesis,<sup>50,65,66</sup> the field has shifted to immunotherapies, mainly checkpoint inhibition but also targeted (vaccination) approaches. Pathway inhibition has maintained momentum, with the biggest change in the last decade being appropriate preselection of subjects based on the proposed mechanism of action.<sup>67</sup> There is a need for academically driven drug development and design of trials with the focus on understanding the mechanisms of response or resistance rather than striving for short-term approval. Similarly, immunotherapy trials should also focus on getting as much information about response and resistance from each subject to inform subsequent steps (backwards translation) and rapid evolution of concepts to trials.

# Treatment of glioblastoma in adults

Wolfgang Wick<sup>ID</sup>, Matthias Osswald, Antje Wick and Frank Winkler

**Abstract:** The diagnosis of a glioblastoma is mainly made on the basis of their microscopic appearance with the additional determination of epigenetic as well as mutational analyses as deemed appropriate and taken into account in different centers. How far the recent discovery of tumor networks will stimulate novel treatments is a subject of intensive research. A tissue diagnosis is the mainstay. Regardless of age, patients should undergo a maximal safe resection. Magnetic resonance imaging is the surrogate parameter of choice for follow up. Patients should receive chemoradiotherapy with temozolomide with the radiation schedule adapted to performance status, age and tumor location. The use of temozolomide may be reconsidered according to methylguanine DNA methyltransferase (*MGMT*) promoter methylation status; patients with an active promoter may be subjected to a trial or further molecular work-up in order to potentially replace temozolomide; patients with an inactive (hypermethylated) *MGMT* promoter may be counseled for the co-treatment with the methylating and alkylating compound lomustine in addition to temozolomide. Tumor-treating fields are an additive option independent of the *MGMT* status. Determination of recurrence is still challenging. Patients with clinical or radiographic confirmed progression should be counseled for a second surgical intervention, that is, to reach another macroscopic removal of the tumor bulk or to obtain tissue for an updated molecular analysis. Immune therapeutic approaches may be dependent on tumor types and molecular signatures. In newly diagnosed and recurrent glioblastoma, bevacizumab prolongs progression-free survival without affecting overall survival in an unselected population of glioblastoma patients. Whether or not selection can be made on the basis of molecular or imaging parameters remains to be determined. Some patients may benefit from a second radiotherapy. In our view, the near future will provide support for translating the amazing progress in understanding the molecular background of glioblastoma in to more complex, but promising therapy concepts

**Keywords:** antiangiogenesis, checkpoint inhibitors, high-LET radiotherapy, malignant glioma, precision medicine, tumor membrane tubes, vaccination

Received: 22 February 2018; revised manuscript accepted: 24 May 2018.

## Background

Glioblastoma is a fatal disease with the majority of patients dying within 15–18 months from diagnosis, with less than 5% of patients alive at 5 years.<sup>1</sup> Even within the more favorable selected clinical trial patient population the 5-year survival rates are around 10%.<sup>2</sup> Age <50 years and a complete macroscopic tumor removal are associated with longer survival; on a molecular level these tumors often exhibit two favorable molecular aberrations: O<sup>6</sup>-methylguanine DNA methyltransferase (*MGMT*) promoter methylation<sup>2,3</sup> or isocitrate dehydrogenase (*IDH*) mutation.<sup>4</sup> There is a large disconnect between enormously

evolving preclinical concepts and a very limited clinical therapeutic armamentarium, which is somewhat resistant to the novel biological concepts, that is, to apply the available biomarkers for treatment decisions, and on the other hand easy to impact by nonconventional strategies, that is, by regionally different one-fits-all approaches with drugs like cannabis, valaciclovir or methadone.

## Epidemiology

The incidence of primary brain tumors between 2007 and 2011 was 21.4 per 100,000 individuals,

with an incidence of gliomas of 6.6 per 100,000 people of which about half were glioblastomas.<sup>1</sup> For reasons unknown, there is regional variability in the incidence. The rate for glioblastoma in Japan is <50% of that in Scandinavia or the United States. The incidence of glioblastoma in general increases with age, with the most pronounced increase in glioblastoma incidence (per 100,000 people) ranging from 0.15 in children and 0.41 in young adults to 13.1 in those aged 65–75 years and 15.0 in individuals between 75 and 84 years of age.<sup>5</sup>

### Risk factors

Overall, manageable risk factors are hardly known. Specifically, therapeutic radiation in long-term survivors seems to have a dose and volume dependent impact.<sup>6</sup> These doses are not reached with diagnostic doses of radiation, for example, by regular cranial computed tomographies (dose in the range of 1–3 milli Sievert, comparable with the annual environmental radiation exposure or a long-distance flight). Relevance of other factors, like cytomegalie virus infection or mobile phone use has not been confirmed. In addition to the well described familial tumor syndromes, there are genetic associations for example, rs4977756 in the cyclin-dependent kinase inhibitor 2A (*CDKN2A*) and the *CDKN2B* gene,<sup>7,8</sup> a retinoic acid modulator *CCDC26* on 8q24,<sup>9</sup> pleckstrin homology-like domain family B member 1 (*PHLDB1*) on 11q23.3,<sup>10</sup> the TP53 (cellular tumor antigen p53) polyadenylation site rs78378222 on 17p13.1,<sup>11</sup> and rs11979158 and rs2252586 in the epidermal growth factor receptor (*EGFR*) gene on chromosome 7<sup>12</sup> with a higher likelihood of glioblastoma in one family.

Also, telomerase reverse transcriptase (*TERT*) and telomerase RNA component (*TERC*), which are both involved in regulating telomere length, have been suggested as interesting candidate genes for increased glioma risk in genome-wide association studies.<sup>13,14</sup>

Overall, until now, there is no firm manageable risk factor, no screening test or prevention concept available for glioblastoma. In turn, there is not role for regular magnetic resonance imaging (MRI) scans in relatives of glioblastoma patients.

### Biological considerations

Glioblastoma is a whole brain disease with a variable focal increase in proliferation generating a

tumor mass, which then may become symptomatic. These days, more weight is put on the largely invisible, diffusely infiltrating part potentially consisting of a functional network of glioblastoma cells (and other brain cells) connected by transmembrane nanotubes (tumor microtubes or ‘TMs’).<sup>15</sup> In addition to the classical hallmarks, such as pathological angiogenesis, necrosis and the immunologically cold environment,<sup>16</sup> these networks not only provide a more stringent concept for the diffuse infiltrative growth, but may also serve as the long-awaited Achilles’ heel for this disease.

### Basic requirement for diagnosis

The diagnosis of a glioblastoma is made tissue-based according to the most recent update of the World Health Organization (WHO) classification of brain tumors including immunohistochemistry and selected molecular tests.<sup>17</sup> Recently, a high-throughput methylation-based classifier<sup>18</sup> has been shown to effectively diagnose glioblastoma based on quantitative methylation classes.<sup>19</sup>

### Standard of care

#### Surgery

The standard of care for adult patients largely irrespective of age, but with a good performance status with radiographically suspected newly diagnosed glioblastoma is a maximal safe surgical resection. This may result in a stereotactic or open biopsy in some patients with tumors in eloquent areas or in a removal of all contrast-enhancing parts of the disease in adequate patients. The goal of a complete macroscopic resection may be reached with the help of intraoperative imaging<sup>20</sup> or fluorescence-guided visualization of tumor tissue with the aid of 5-aminolevulinic acid.<sup>21,22</sup> As long as the community is not prepared to complete a controlled trial on the relevance of resection at progression, we will base our recommendations for a second surgery on some pragmatism, the need for an updated molecular or tissue diagnosis in cases with molecular-directed treatment options, the need for reduction of global or focal intracranial pressure, local expertise and patient preference.

#### Radiotherapy

Radiotherapy, together with surgery, has been the mainstay treatment in the management of patients

with glioblastoma since the 1970s and the combination of both doubles overall survival in patients with malignant gliomas.<sup>23,24</sup> Little clinical progress was made over the past decades. The prognosis of patients with glioblastoma remains poor with median survival of ~14 months after adjuvant temozolomide-based radiochemotherapy<sup>2,25</sup> with relevant predictive impact of inactivation of the methylguanine DNA methyltransferase gene promoter.<sup>26</sup> Local recurrence within 2.0 cm of the pre-surgical initial tumor margin is the main pattern of failure following treatment of glioblastoma;<sup>27,28</sup> a biomarker helping to dissect responding patients is missing. Delineation of target volumes by metabolic imaging and more sophisticated MRI techniques with focus on tumor areas with a need for higher doses or better sparing of sensitive structures is in the center of most research to optimize radiotherapy. A second pillar with little news to report is the assessment of radiosensitizers. The third aspect at least in sites with the respective technical prerequisites is the emergence of heavy ion radiotherapy using carbon ions (CIR) and raster scanning technique demarcating a landmark development in the field of high precision radiotherapy.<sup>28</sup> High precision radiotherapy holds the promise in escalating the dose in the tumor and improving local control while sparing normal tissue.<sup>26</sup> However, previous data indicate that escalating the dose alone will not suffice to improve outcome in these radioresistant tumors in the clinic. Conceptually, precision radiotherapy is an effective therapy with intrinsic limitations in highly infiltrative disease. In our view, more weight may be put on integrating radiotherapy into current biological concepts, for example, into immunotherapy, for example, by understanding 'remote', so-called abscopal (bystander) effects.<sup>29</sup> As already discussed in the surgery section, implementation of novel radiation qualities or planning strategies would require controlled trials. Similarly, it is surprising to realize that despite many thousand patients being treated each year with radiation, molecular biomarkers to predict response are still lacking.<sup>30,31</sup>

### Chemotherapy

To date, the landmark contribution of the European Organization for Research and Treatment of Cancer (EORTC) with the EORTC 26981 trial defines the standard of chemotherapy, that is concomitant treatment with temozolomide at 75 mg/m<sup>2</sup> body surface, on empty stomach approximately 2 h prior to the radiotherapy

session and fasting in the mornings or later after breakfast of nonradiation days. Adaption is made with treatment pauses according to blood counts and a *Pneumocystis jirovecii* pneumonia prophylaxis is recommended especially in lymphocytopenic individuals. There is a 4-week break and the chemotherapy is completed by six maintenance cycles of temozolomide on 5 out of 28 days at 150 mg (cycle 1) and at 200 mg (cycles 2–6)/m<sup>2</sup> body surface adapted according to general and more specifically hematological tolerance.<sup>2,25</sup> Again, supportive measures may include a PCJ prophylaxis and an antiemesis. Steroid use is regarded a negative factor for the efficacy of treatment.

Neither the adaption of the schedule, for example, 21/28 days or 7/14 days temozolomide in the maintenance phase<sup>32,33</sup> nor the longer exposure<sup>34</sup> has a proven impact to date.

### Impact of molecular diagnostics

According to the most recent adaption of the WHO classification, *MGMT* promoter methylation is predictive for efficacy and response to alkylating and methylating chemotherapy agents<sup>2,26</sup> in glioblastoma. Long-term surviving patients have >90% glioblastoma with methylated *MGMT* promoter<sup>2</sup> versus 35% in the general glioblastoma patient population.<sup>35</sup>

*IDH1/2* mutations are relevant positive prognostic factors and in glioblastoma strongly associated with glioblastoma progressive from a lower grade glioma.<sup>36</sup> The existence of *de novo IDH*-mutated glioblastoma is a topic of controversy.

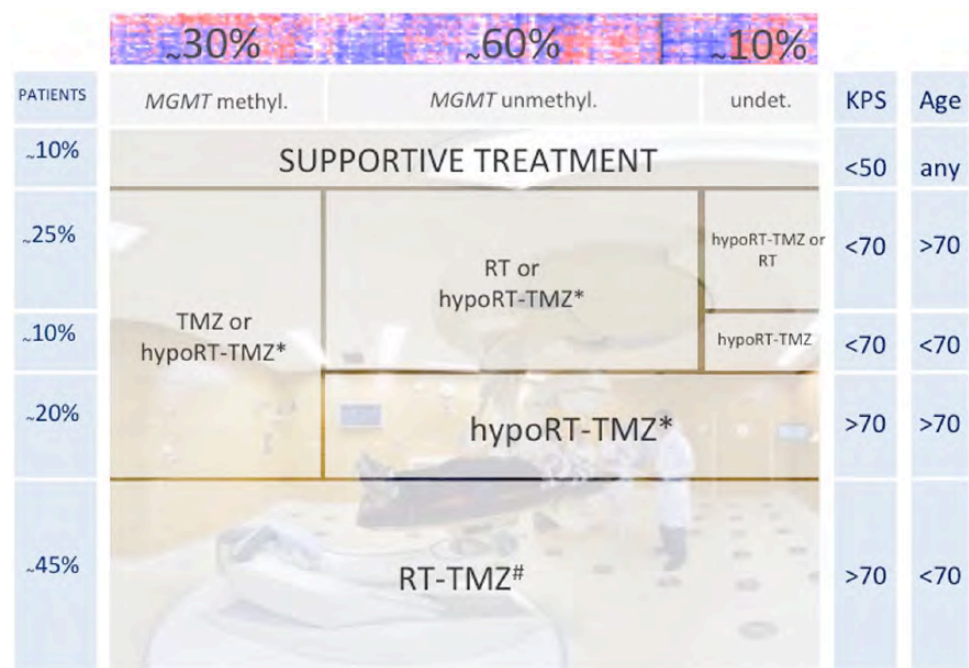

There is no consistent correlation of EGFR amplification with survival, largely irrespective of the age at clinical manifestation. The variant III of EGFR seems to get lost in the progression at least of a fraction of patients.<sup>37</sup> Loss of heterozygosity (LOH) 10q is the most frequent genetic alteration in glioblastoma and is associated with reduced survival. The presence of PTEN mutations is not associated with prognosis of glioblastoma patients.<sup>17,38</sup>

### Adaptions/options to the standard in newly diagnosed patients

#### Elderly patients

The Scandinavian Neuro Oncology Network, the Neurooncology Working Group of the German

**Figure 1.** Therapy options and recommendations for patients with glioblastoma in different age groups according to Karnofsky performance status.<sup>41</sup> Prevalence (according to CBTRUS, 1) is depicted by the size of the boxes (adapted from Wick and colleagues, 2018).<sup>42</sup>

Cancer Society (NOA) as well as the CCTG (Canadian Cancer Trials Group) and the EORTC have provided randomized data for the treatment of elderly patients with glioblastoma. These trials provide evidence that hypofractionated radiotherapy over 3 weeks is equivalent to longer treatment and that chemoradiation using that shorter radiotherapy with temozolomide as well as maintenance temozolomide is superior to radiotherapy alone.<sup>39</sup> In the absence of comparative data between regular fractionated and hypofractionated chemoradiotherapy as well as a lack of these data compared with temozolomide alone leaves room for individualized treatment decisions based on clinical assumptions, but not data. Today, increased age (>65/70 years), relevant comorbidities, Karnofsky performance status (<70) and some considerations on frailty are used to provide guidance (Figure 1). Molecular testing is of some help. It has revealed a low prevalence of favorable prognostic markers in elderly patients.<sup>40</sup> The virtual absence of IDH mutations in patients over the age of 65, according to the new WHO classification, suggest that differential prognosis is not based solely on age but rather that separate entities exist with a distinct age distribution.<sup>38</sup> The prevalence of *MGMT* promoter methylation is

similar to that in younger patients. Specifically, in the elderly patients a string call was made for the use of *MGMT* as a predictive biomarker.<sup>26,39</sup>

Treatment according to *MGMT*

Current (European) guidelines are explicit that only in elderly or frail patients the use of temozolomide can be adapted according to the methylation of the O6-methylguanine DNA methyltransferase gene promoter. Otherwise, *MGMT* testing though performed with increasing frequency has no practical impact in the management of patients. Some centers take recent data on the *MGMT*-dependence of response to temozolomide<sup>43</sup> or lomustine<sup>44</sup> at glioblastoma progression as decisive to not expose patients again to alkylating or methylating chemotherapies at progression, but this concept is neither generally supported nor explicitly stated in our guidelines. Trials in patients without *MGMT* promoter methylation<sup>26</sup> showed that leaving out temozolomide from first-line treatment was of no detriment to patients, challenging the view that temozolomide should be used in every patient despite the absence of *MGMT* promoter methylation. Recent data might further help to decipher

the benefitting patient population. TERT expression may be necessary to ensure the *MGMT* methylation related benefit to alkylating chemotherapy.<sup>45</sup> Overall, *MGMT* status testing without taking consequences is unsettling for patients, creates a lot of second consulting and finally undermines trust in our profession. On the other hand, testing offers the opportunity to safe patients a treatment with no or little chances for help plus offers options for alternatives, which should be based on further precision measures by looking for molecular lesions potentially relevant for targeted or immunotherapies (see Outlook). This should be avoided in patients <70 years without the patient-physician team willing to take any consequences.

### Use of tumor-treating fields

Tumor-treating fields (TTFields) use alternating electrical fields to inhibit mitoses *via* disruption of the spindle apparatus. In a randomized trial that was published originally in *JAMA*, the addition of TTFields to standard radiotherapy (RT) and temozolomide (TMZ) in newly diagnosed glioblastoma extended overall survival [hazard ratio (HR), 0.64 (99.4% confidence interval (CI), 0.42–0.98);  $p = 0.004$ ].<sup>46</sup> The effect of the fields is maintained at long-term (final) analysis,<sup>47</sup> though the selected patient group, the lack of a control for the more active supportive care and the relatively small difference in long-term survival at 5 years compared with the EORTC trial<sup>2</sup> raised questions in the ‘expert’ community. Whether the magnitude of overall survival increase outweighs the individual burden and the societal cost is yet to be determined. The long-term relevance of the fields will be determined by whether they are routinely integrated into daily practice and the success (or not) of other concepts discussed below.

## Concepts at recurrence

### Re-surgery

As already stated above, we might consider reoperation to improve symptoms, in the case of early progression in patients in whom initial surgery was not adequate or later progressors, when the initial treatment might just be repeated. We are uncertain about the effect of second surgery on overall survival. It is considered that another gross total resection of enhancing tumor<sup>48</sup> is relevant,

but prospective controlled data are lacking. Recently, there is an increasing demand for post-progression tissue extraction as targeted treatments may offer valid options and also therapy with checkpoint inhibitors<sup>49</sup> should be restricted to patients with the most likely benefit.

### Re-radiotherapy

The efficacy of re-irradiation is uncertain until date. Its appreciation varies between sites, countries, recurrence pattern and with the time interval to the first treatment. Fractionation depends on tumor size. Fractionation between 2.0 and 2.4 Gy has been tested, but also higher doses per fraction of 5–6 Gy using stereotactic hypofractionated radiotherapy to a total dose of 30–36 Gy, and also radiosurgery with a single dose of 15–20 Gy. Overall toxicity seems not to be the main issue.<sup>50</sup> As with systemic therapies, there is a lack of relevant efficacy, for example, progression-free survival rate of 3.8% at 6 months in the APG101 randomized trial at 18 fractions of 2 Gy.<sup>51</sup> There is a clear need of a definition for a population candidate for re-irradiation, research on biomarkers involved in radioresistance<sup>52</sup> and also trial concepts that provide controlled information on whether or not this is a reasonable approach. The aforementioned applies to conventional photon therapy and may or may not be challenged if different radiation qualities, like C<sup>12</sup> ions or protons are being used.

### Chemotherapy at progression

Most studies at progression are of limited size therefore impacted by the heterogeneity of the disease, non-comparative or fail to use a control arm lacking the experimental drug. In addition to re-exposure to temozolomide at standard dose, most patients will receive one of the nitrosoureas, that is, carmustine (BCNU), lomustine (CCNU), or fotemustine. They alkylate at the N<sup>7</sup> and O<sup>6</sup> positions of guanine and introduce interstrand crosslinks as well as act by carbamoylation of amino acids interfering with transcriptional, translational and posttranscriptional processes.<sup>53–56</sup> These are DNA alkylating and methylating agents that cross the blood–brain barrier and have been extensively used in glioma treatment. They may induce considerable hematological toxicity with long-lasting bone marrow suppression, liver and renal toxicity, and, specifically carmustine, interstitial lung disease. Efficacy is dependent on *MGMT* status both in the

AVAREG trial<sup>57</sup> and also in the EORTC 26101 trial.<sup>44</sup> At the same level, temozolomide re-exposure is only meaningful if patients are diagnosed with a progressive glioblastoma harboring a methylated *MGMT* promoter.<sup>43</sup> It may be extrapolated from the BR12 trial that used standard dose and dose-intensified temozolomide after radiotherapy alone (and not re-challenge after temozolomide)<sup>58</sup> and the dose-dense maintenance treatment of RTOG 0525<sup>32</sup> that conventional (5 out of 28 days) chemotherapy is not inferior to any dose-intensification<sup>43</sup> and the latter may not be used unless new data appear.

#### *Experimental options at progression*

Certainly, many treatments can be tried in patients with progressive glioblastoma after the above mentioned. As present, we would recommend trial participation. Also, performance status and the general situation are impacting options. In the United States, bevacizumab is approved and may offer a further treatment line with the promise of prolonging progression-free survival and potentially in selected patients also overall survival. In the European Union, this option is very restricted due to a lack of approval. Here, we recommend a pragmatic approach that involves obtaining post-progression tissue and assess for potential molecularly informed treatment decisions.<sup>59</sup> The fields although sometimes advertised differently did not hold the promise at progression therapy.<sup>60</sup>

### **Outlook**

#### *Antiangiogenesis*

After the failure of bevacizumab to demonstrate an effect on overall survival in newly diagnosed patients,<sup>61</sup> the subsequent randomized, phase III EORTC 26101 compared lomustine with or without bevacizumab at progression. Despite prolonging progression-free survival (HR 0.49; CI 0.39, 0.61), combined lomustine and bevacizumab treatment does not confer an overall survival advantage (HR 0.95; CI 0.74, 1.21;  $p = 0.650$ ) over treatment with lomustine alone in patients with progressive glioblastoma.<sup>44</sup> In this study, crossover to bevacizumab occurred in 35.5% of patients in the control arm; whereas 18.7% of patients in the combination arm continued bevacizumab at progression. However, bevacizumab

continues to play a role in the treatment of glioblastoma in large areas of the world. Many practicing clinicians regard its positive effect on progression-free survival, and other palliative effects, and neurological improvement seen in many patients as meaningful benefits, in the absence of any overall survival gain in the entire patient population. Pragmatically, bevacizumab with its documented beneficial effect on radionecrosis-related edema and neurological dysfunction<sup>62</sup> might be particular interesting for patients with radiological and clinical deterioration, frequently called 'pseudoprogression'.

#### *Immunotherapy*

Immunotherapy is regarded a valid option for patients with glioblastoma though data to prove this hypothesis are largely confined to case reports and by analogy to the successes in other malignancies. Independent of the approach (e.g. checkpoint inhibition, targeted vaccine, adoptive T-cell transfer), the clonal representation of the target antigen and the immunosuppressive microenvironment have to be taken into account for clinical development. For instance, EGFR vIII is a subclonal antigen with heterogeneous expression in the tumor tissue, which may, in theory, be subjected to immune evasion. Despite promising initial data, a large phase III trial failed.<sup>37</sup> VXM01 is encoding vascular endothelium growth factor receptor 2 (VEGFR2) in order to evoke an immune response specifically directed against the tumor vasculature. It is currently in clinical development as a treatment for solid cancer types. The oral T-cell vaccine platform of the company VAXIMM is based on the approved, live attenuated *Salmonella typhi* vaccine strain Ty21a, which has been applied in millions of individuals for prophylactic vaccination against typhoid fever.<sup>63</sup> IDH1R132H<sup>64</sup> and H3.3K27M<sup>65</sup> as early founder mutations represent clonal antigens, but controlled clinical data on their relevance are yet to be generated. The Glioma Actively Personalized Vaccine Consortium (GAPVAC) realized an immunotherapy, for which the selection of actively personalized peptide vaccines (APVAC) for treatment of newly diagnosed glioblastoma was based not only on whole-exome sequencing but also on human leukocyte antigen (HLA)-ligandome analyses providing information of the actual presentation of relevant epitopes in the tumor. Mutated peptides identified by next

generation sequencing and mass spectrometry may not only be used for peptide vaccination, but serve as a platform for personalized immunotherapies with potentially more aggressive cell-based treatments. Controlled clinical trials assess the efficacy of nivolumab in progressive and newly diagnosed glioblastoma. Whereas the trials in newly diagnosed patients separated according to *MGMT* promoter methylation status are ongoing, results from the study in progressive glioblastoma comparing nivolumab and bevacizumab have been reported. A total of 369 patients, progressive after standard of care, were randomized to nivolumab 3 mg/kg every 2 weeks ( $n = 184$ ) or bevacizumab 10 mg/kg every 2 weeks ( $n = 185$ ). Progression-free survival was superior in the bevacizumab arm (HR = 1.97; 1.57, 2.48) with medians of 3.5 months (2.9, 4.6) and 1.5 months (1.5, 1.6), respectively. There was no signal for any difference in overall survival in this unselected patient population (HR=1.04; 0.83, 1.30;  $p=0.76$ ) with medians of 10.0 months (9.0, 11.8) for bevacizumab and 9.8 months (8.2, 11.8) for nivolumab.<sup>66</sup> Nivolumab or temozolomide in combination with radiotherapy in newly diagnosed patients with *MGMT*-unmethylated glioblastoma are treated in CheckMate 498. CheckMate 548 assesses nivolumab or placebo in combination with radiotherapy and temozolomide in patients with *MGMT*-methylated or indeterminate glioblastoma at first diagnosis. These trials also do not enrich for patients more likely to benefit from the immune intervention.<sup>67</sup>

Checkpoint inhibitors in glioblastoma may work only with a specific immunogenic background, potentially to be defined by MSI-H or dMMR, or with associated treatment, for example, vaccination. The most prominent checkpoints in other malignancies may not be the most relevant in glioblastoma;<sup>68</sup> other factors like the CD95 system, tryptophan-2,3-dioxygenase (TDO)<sup>69,70</sup> or other programmed death family members<sup>71</sup> may be of greater importance. In addition to being restrictive based on molecular stratification, there are concepts in development that promise a stronger immunoeffect. Several chimeric antigen receptors are in clinical development for glioblastoma. The currently available data are for interleukin 13 receptor (IL13R)- $\alpha$ 2, EGFR variant III, and HER2 as targets. There are already cases and small series showing feasibility of delivery and manageable toxicity,<sup>72</sup> but

translational research regarding efficacy and resistance mechanisms are ongoing.<sup>73,74</sup>

### Targeted treatments

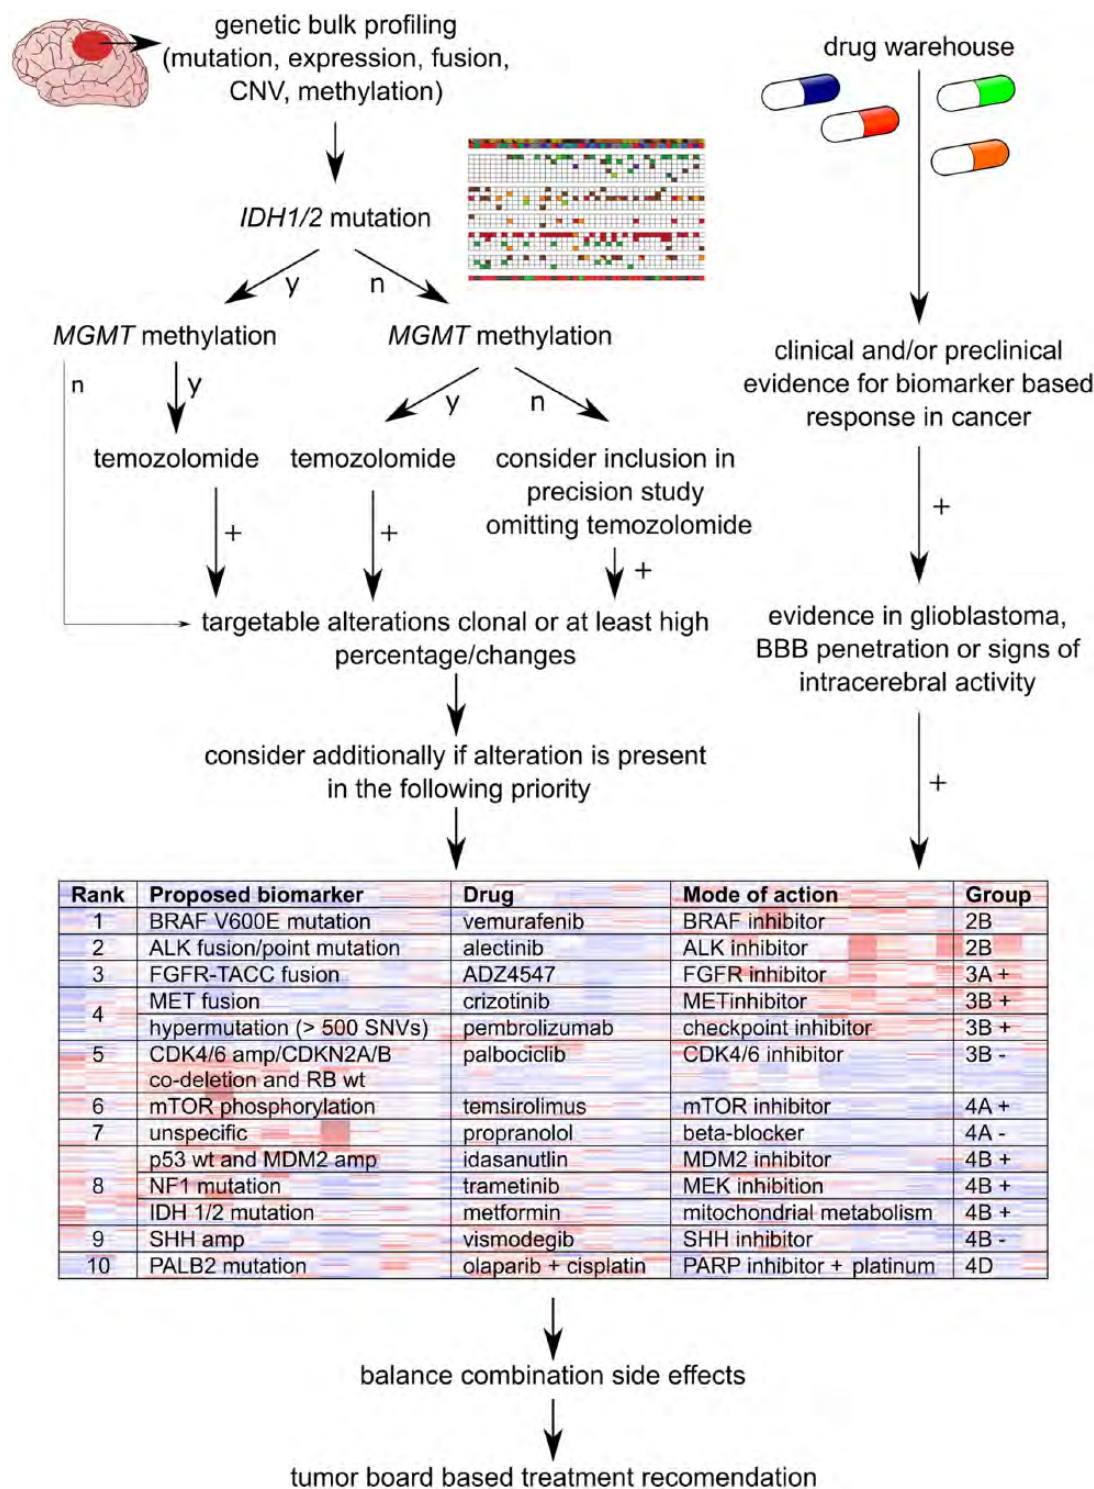

Biomarkers that predict response and ultimately benefit from a given therapy plus an effective treatment are the cornerstones of precision neuro-oncology. *MGMT* is a good example for a predictive biomarker in the field of gliomas.<sup>26,41</sup> However, no officially accepted (accredited) test exists. Further, it is possible that predicting response to temozolomide is more complex than by just determining *MGMT* methylation status. The delineation of the right subgroups may also involve global methylation profiles and TERT status.<sup>75,5</sup>

Please find a strategy for treatment of newly diagnosed or recurrent glioblastoma and examples of putative predictive biomarkers in Figure 2. Importantly, the prerequisite until now is a tissue sample from the tumor that needs treatment (and not just archival information).

Further, there are interesting examples of drug repurposing with less intuitive compounds for the glioblastoma field. Also, these compounds may deserve testing in an otherwise difficult clinical situation and with indicative biomarkers associated (Table 1). In a pilot series that serves as model for the examples provided in the current review, compounds were recommended in combinations, following the concept that blocking multiple pathways with combination therapy may be more effective than single agent therapy especially when treating recurrent, progressive glioblastoma.<sup>59</sup>

Therefore, well-considered allocation of newly diagnosed as well as progressive patients to clinical trials based on molecular characteristics of the tumor as well as necessary retrospective validation of potential biomarkers are essential in a clinical setting. A current concept prospectively using biomarkers to enrich for potentially benefitting patients is the Nationales Centrum für Tumorerkrankungen (NCT) Neuro Master Match (N<sup>2</sup>M<sup>2</sup>), a trial of molecularly matched targeted therapies plus radiotherapy in patients with newly diagnosed glioblastoma without *MGMT* promoter methylation.<sup>76</sup> The Glioblastoma Adaptive, Global, Innovative Learning Environment (AGILE) consortium is planning to take a differential approach by reassessing potential

**Figure 2.** Sketch to show a way towards precision. Putative work flow from a glioblastoma tissue sample. BBB, blood-brain barrier; CNV, copy-number variation; GBM, glioblastoma; IDH, isocitrate dehydrogenase; MGMT, O6-methylguanine DNA methyltransferase; n, no; y, yes.

biomarkers from an unselected cohort with given therapies first and integrating these information via adaptive processes to enrich while the trial accrues.<sup>77</sup>

**Table 1.** Options for molecular adapted treatments [according to Byron and colleagues and Pfaff and colleagues].<sup>59,76</sup>

Molecular lesion	Signaling pathway	Potential therapy
Neurofibromatosis 1 (NF1) gene alteration	MEK	Trametinib
Loss of partner and localizer of BRCA2 (PALB 2) or BRCA	PARP	Olaparib and cytotoxic agent
IDH mutation	IDH - methylation	Alkylating agents, demethylating agents (5-azacytidine, decitabine), metabolic agents (metformin)
MutS protein homolog (MSH)6, MSH4, MSH5, postmeiotic segregation increased (PMS)1, PMS2, MutL homolog (MLH)1, and MLH2 mutations or hypermutator phenotype, DNA polymerase epsilon catalytic subunit (POLE) mutation	Checkpoint inhibition	Pembrolizumab, nivolumab
Proneural (IDH-wildtype) expression pattern	Anti-VEGF	Bevacizumab
Lower levels of methylation of the CpG2 in the promoter of the CD95 ligand	CD95/CD95ligand	Asinercept
IDH, isocitrate dehydrogenase; MEK, mitogen-activated protein kinase; PARP, poly(ADP-ribose)-polymerase; VEGF vascular endothelial growth factor

# Alternating Electric Fields Therapy for Malignant Gliomas: From Bench Observation to Clinical Reality

Eric T. Wong<sup>a, b</sup> • Edwin Lok<sup>a</sup> • Kenneth D. Swanson<sup>a</sup>

<sup>a</sup>Brain Tumor Center and Neuro-Oncology Unit, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA, and <sup>b</sup>Department of Physics, University of Massachusetts in Lowell, Lowell, MA, USA

## Abstract

Alternating electric fields of intermediate frequencies, also known as Tumor Treating Fields (TTFields or TTF) is a novel anticancer treatment modality that disrupts tumor cell mitosis at the metaphase–anaphase transition, leading to mitotic catastrophe, aberrant mitotic exit, and/or cell death. It is realized through alteration of the cytokinetic cleavage furrow by interference of proteins possessing large dipole moments, like septin heterotrimer complex and  $\alpha/\beta$ -tubulin, and that results in disordered membrane contraction and failed cytokinesis. Aberrant mitotic exit also elicits immunogenic cell death, which may potentiate an immune response against treated tumors. Notably, in patients with recurrent glioblastoma multiforme (GBM) a prospective clinical trial demonstrated comparable overall survival and progression-free survival after TTFields therapy and best physician's choice chemotherapy. Moreover, it was shown that in patients with newly diagnosed GBM initially treated with standard chemoradiotherapy with daily temozolomide (TMZ), adjuvant TTFields combined with TMZ offered better survival than adjuvant TMZ alone. Therefore, TTFields therapy can be appreciated as a standard treatment option in cases of intracranial malignant gliomas, whereas future studies should establish its optimal combination with other existing anticancer modalities, which may offer additional survival benefits for patients.

## Introduction

Exposure of cells to non-ionizing, alternating electric fields can have different consequences depending on the frequency. For instance, at frequencies of 1 kHz or lower, it causes depolarization of the membrane potential in excitable cells, such as neurons, cardiac myocytes, and muscle cells, via the opening of voltage-gated ion channels [1–3]. Defibrillators and electroshock therapy both rely on the ability of low frequency, high

intensity electric fields to induce membrane depolarization. On the other hand, within a narrow range of intermediate frequencies (with a peak activity at 100–200 kHz) alternating electric fields, also known as Tumor Treating Fields (TTFields or TTF), are able to perturb cancer cells during mitosis, affecting their physiology by the induction of minute forces on intracellular proteins possessing high dipole moments [4].

Both experimental models and clinical studies in patients with glioma demonstrated that TTFields therapy resulted in tumor regression [5–7]. Based on favorable data from a phase III clinical trial a device designed to deliver such treatment in humans, the NovoTTF-100A (Optune®; NovoCure Ltd., Haifa, Israel), has been approved by the US Food and Drug Administration (FDA) for management of recurrent glioblastoma multiforme (GBM) [8, 9]. Furthermore, analysis of a second phase III trial has shown that in patients with newly diagnosed GBM initially treated with standard fractionated radiotherapy (FRT) concomitant with daily temozolomide (TMZ), adjuvant TTFields therapy combined with TMZ offers better survival than adjuvant TMZ alone [10].

### Basic Mechanisms of TTFields Therapy

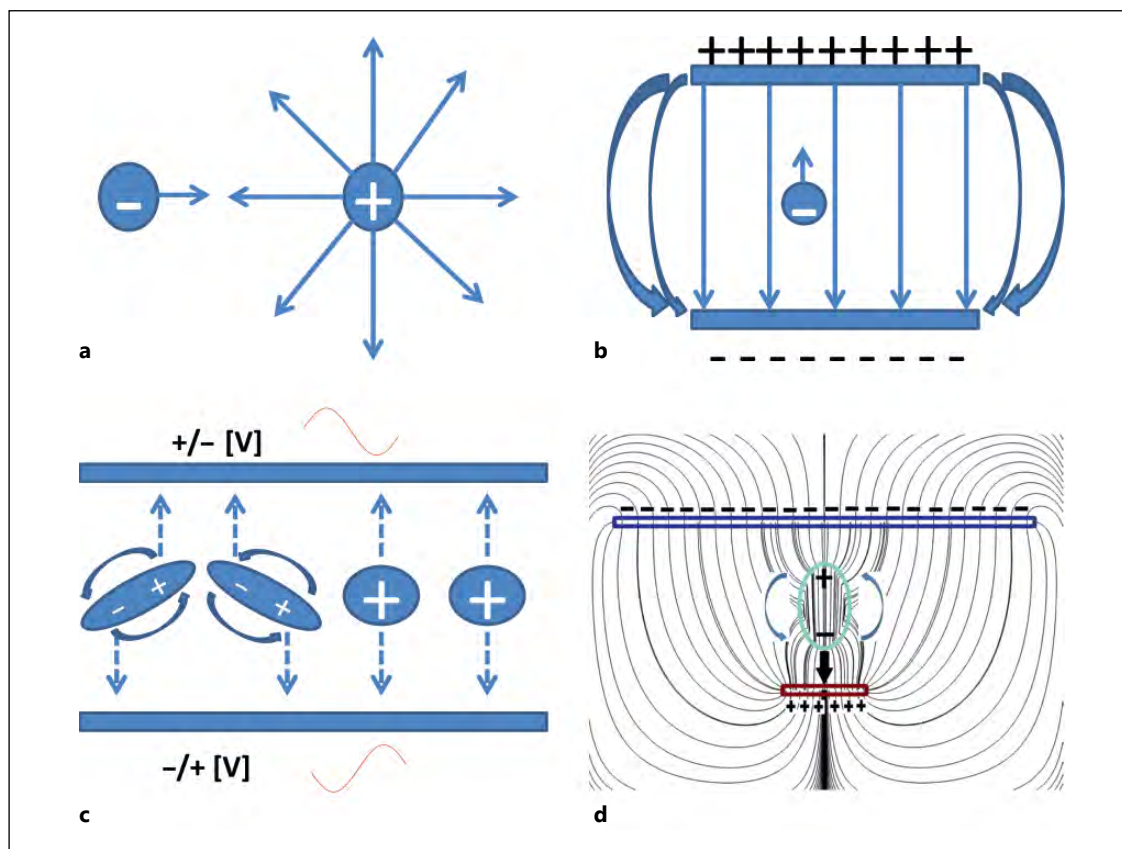

The basic mechanisms of chemotherapy and irradiation usually involve triggering G1/S or G2/M cell cycle checkpoints, as well as spindle poisons mediating a block in metaphase by initiating the spindle assembly checkpoint. By contrast, the cells exposed to TTFields during mitosis showed normal entry into metaphase, but exhibited random and uncontrolled violent plasma membrane blebbing that coincided with metaphase exit [4, 5].

#### *Induction of a Mechanical Force on Protein Dipoles*

Most intracellular proteins do not have static point charges. Instead, they possess dipole moments produced by discontinuities of the exposed charges on their surfaces arising from charged amino acid moieties or bound nucleotides. The size of the dipole moment of a protein is a function of the magnitude of negative and positive charge separation and the distance between the differentially charged regions.

In a static electric field, positively charged molecules will migrate toward the negatively charged pole, while a negatively charged molecule will migrate towards the positively charged pole. This behavior differs in an alternating electric field, since any movement in one direction will be canceled out when the field switches polarity. However, even though there is no net translational movement, alternating changes in the electric fields polarity can induce rotational or torsional movements of molecules possessing dipoles (Fig. 1). In this way, TTFields of intermediate frequency probably produce stresses on certain proteins possessing high dipole moments and impact their intracellular function [11]. These properties most likely constitute the basis for the cellular disruption seen during mitosis in exposed cell cultures, characterized by induced violent plasma membrane blebbing and leading to cell death [4, 5].

**Fig. 1.** Behaviors of point charge and dipole in static and alternating electric fields. When it encounters a point source, a negative point charge migrates toward a positive source (a). In a parallel plate, a negative point charge migrates toward the positive plate (b). When point charges are exposed to alternating electric fields there is no net translational movement, but for dipoles there are rotational or torsional movements that vary according to the frequency of time-varying electric fields (c). When a dipole is exposed to a time-varying, non-uniform electric field (dielectrophoresis [d]), there are both translational and torsional movements.

### *Alterations of Mitotic Function during Cytokinesis*

Mitosis is a meticulously orchestrated event wherein various structures being rapidly and precisely assembled to function as cells progress from prometaphase to telophase and then to daughter cell formation. All of these cellular machineries must be executed with both temporal and spatial precision, which also creates its potential vulnerability to various perturbations. The observation that TTFs disrupt cells during mitosis [4, 5] strongly suggested their interaction with one or more processes critical to cell division.

During preparation for mitosis, the replicated centrioles migrate towards the opposite poles of the dividing cell. As mitosis proceeds, they nucleate microtubules that form the metaphase spindle radiating towards and meeting near the cell's equatorial

center. The condensed chromosomes migrate along the spindle microtubules until they reach this midpoint, forming the mitotic (metaphase) plate. Later, the paired kinetochores on each sister chromatid capture the ends of microtubules within opposing metaphase spindles. This acts to not only align the constituent chromatids of each chromosome towards the poles of the forming daughter cells, but also creates tension across the kinetochores. Tensionless kinetochores produce a signal that acts on the E3 ubiquitin targeting subunit of cell-division cycle protein 20 (Cdc20) of the anaphase-promoting complex, also called the cyclosome (APC/C<sup>Cdc20</sup>). Cdc20 exists in either an active or inactive form and the signal from tensionless kinetochores favors the inactive conformation. Since a single uncaptured kinetochore produces sufficient signal to prevent APC/C<sup>Cdc20</sup> activation, metaphase exit only proceeds after the last chromatid is captured. Upon activation, APC/C<sup>Cdc20</sup> targets the ubiquitin-mediated destruction of proteins, including cyclin B and securin, which maintain cells in metaphase [12, 13]. Once these proteins are destroyed, cells irrevocably proceed into anaphase [12, 14–17] and cytokinesis [18].

The cytokinetic cleavage furrow (CCF) formed by anaphase spindles between the separated chromosomes creates coordinated forces necessary for division of the parental cell. Separation of the daughter cells is the result of ingression by the CCF and its constriction around the equatorial fission plate, which is driven by non-muscle myosin II (NM II) activity [19–21]. The anaphase spindle midline contains proteins that are critical for proper CCF localization and function [22–25]. Centralspindlin complex (composed of KIF23 and MgcRacGAP dimers) recruits the structural domain of guanine nucleotide exchange factors (RhoGEF) of the epithelial cell transforming 2 (ECT2) protein early in anaphase [26] from where it is subsequently and rapidly delivered to the CCF [27]. ECT2 then binds the adaptor protein anillin, which in turn binds to both the septin 2, 6, and 7 (SEPT2-SEPT6-SEPT7) heterotrimer [28] and NM II. Together, these proteins cooperate in the recruitment, localization, and regulation of the contractile elements within the CCF responsible for producing the forces necessary for cytokinesis. The septin complex plays a critical role in demarcating the lateral boundaries that limit NM II activation to the equator of the cell above the fission plate, constraining its contraction to the CCF [29]. In addition, ECT2 protein has been shown to be required for the stability of the anaphase spindle midline, which becomes disordered upon its depletion in mRNA knockdown experiments [30].

Our studies of cells treated with TTFields did not demonstrate differences in mitotic progression through either prometaphase or metaphase, or in the rates of cyclin B and securin degradation, findings that suggest normal capture of microtubules by kinetochores. However, the timing of the violent membrane blebbing was consistent with the timing of metaphase exit [4]. These data indicate that TTFields affect cells within the metaphase-anaphase transition and strongly suggest that membrane blebs are likely the result of plasma membrane rupture from cell surface cytoskeleton. These observations have significant implications on the clinical use of TTFields in cancer treatment. Unlike other therapies that induce damage triggering the G1/S, G2/M, or

spindle assembly checkpoints, alterations of the cellular machineries after they have committed to anaphase are not correctable and invariably lead to mitotic catastrophe, aberrant mitotic exit, and cell death [18]. Since there is little overlap between the effects of TTFields and the mechanisms of action of most other available anticancer therapies, combined treatment strategies are readily possible.

### *Molecular Targets of TTFields*

As mentioned above, TTFields are likely to affect molecular targets that possess sufficiently high dipole moments and are needed for the proper functioning of the CCF. The SEPT2-SEPT6-SEPT7 complex [31] has a very high dipole moment of 2711 debyes (D), and it has a directional vector that is orthogonal to the longitudinal axis of the heterotrimer. For comparison, this dipole moment is 5 standard deviations greater than the median value of 542.66 D for intracellular proteins [32]. Given the critical role of SEPT2-SEPT6-SEPT7 complex in regulating CCF function and its large dipole moment, we considered it as a potential target for TTFields action (Fig. 2). Of note, knockdown of SEPT6 or SEPT7 also results in CCF dysfunction leading to violent membrane blebbing and aberrant mitotic exit [29, 33].

The SEPT2-SEPT6-SEPT7 heterotrimers align parallel to each other along longitudinal axes of the anaphase spindle midline and CCF [31, 34–36]. Since the direction of dipole moment vector is orthogonal to this axis, TTFields predictably induce rotational or torsional movement around it, preventing the assembly of the higher-order septin structures. Analysis of septin localization in anaphase showed a significant decrease in anaphase spindle and CCF accumulation in cells treated with TTFields, demonstrating that this therapy is able to alter septin behavior during mitosis. In addition, anaphase spindle midlines were shown to be disordered, which may play a major role in producing the observed catastrophe during anaphase. It is unclear, however, whether the CCF perturbation is the result of the disordered anaphase spindle midline, the failed recruitment of septin to CCF, or both. Nevertheless, these data support a model in which perturbation of septin function by TTFields during anaphase results in membrane blebbing and that disrupts the dividing cell.

The  $\alpha/\beta$ -tubulin dimer, which also has a high dipole moment of 1660 D, represents another possible therapeutic target of TTFields. It supports an alternative hypothesis for the disordering of the anaphase spindles, which proposes that rapid microtubule dynamics may make this spindle more vulnerable to disruption at the level of microtubule polymerization [4]. Since astral microtubules help in delivering and/or controlling small GTPase RhoA (Ras homolog family, member A) activity within the CCF [30, 37], TTFields could produce sufficient disruption of microtubule dynamics that alters the delivery of these components and thus contributes to the induction of CCF dysregulation. While our experiments did not demonstrate gross differences in microtubule structures in fixed metaphase or spreading cells, it is possible that therapy-induced perturbations of microtubules during mitosis were undetectable.

**Fig. 2.** Mechanism of action in septin-based model of TTFields therapy. Septin 2, 6, and 7 heterotrimer (a) possesses a dipole moment of 2711 D, which is 5 standard deviations greater than the average for intracellular proteins. The directional vector of this dipole is orthogonal to the longitudinal axis of the complex and TTFields can induce rotation around this axis (b). This interfere with the formation of the higher-order septin structures required to complete mitosis. During mitosis (c), cells experience nuclear envelope breakdown and chromosome condensation (blue) in prometaphase, with further formation of the metaphase plate by chromosome congression to the midpoint of the metaphase spindle (yellow). During anaphase, septin 2, 6, and 7 heterotrimers normally localize to the anaphase spindle midline and cytokinetic cleavage furrow (CCF) to support their stability and function. Perturbation of normal CCF assembly by TTFields results in mitotic catastrophe, leading to aberrant mitotic exit followed by cell death.

Finally, given the vulnerability of cells to disruption during mitosis, other proteins, in addition to septin and  $\alpha/\beta$ -tubulin, may also be affected by TTFields. The alteration of multiple different protein species in aggregate might be required to produce the violent membrane blebbing observed in exposed mitotic cells.

### *Apoptosis and Immunogenicity*

Aberrant mitotic exit induced by TTFields can potentially lead to cell death, which is likely caused by an unresolved mitotic spindle apparatus, multiple centrioles, and/or the presence of supernumerary chromosomes [4, 38]. According to our data, G0/G1 cell cycle arrest and increased rates of apoptosis are observed within 36 h of exposure to TTFields, which indicates that cells exiting mitosis following treatment are significantly deranged and suggests that the clinical efficacy of this therapy may somewhat depend on tumor genetics.

There are at least two known forms of programmed cell death [39]. The first one, homeostatic apoptosis, leads to an orderly cell death resulting in the production of plasma membrane blebs that create small cell fragments ready for removal by phagocytes. Such cellular fragments also suppress the inflammatory effector functions by simultaneously upregulating phosphatidylserine (Ptd-L-Ser) on the cell surface, which limits immune damage during wound healing or organogenesis. In contrast, the second form, known as immunogenic cell death (ICD), acts similarly to the early immune defense against viral infection. It also results in Ptd-L-Ser exposure on the cell surface, but can elicit an active immune response against the dying cell through expression of the endoplasmic reticulum chaperone calreticulin [40] and secretion of both ATP and high mobility group box 1 (HMGB1) protein [39]. Calreticulin promotes phagocytosis by innate immune cells, while ATP and HMGB1 protein act as chemotactic factors that activate immune effectors and stimulate antigen presentation function [39].

Aberrant mitotic exit elicits ICD [41]. Moreover, cells treated with TTFields demonstrated increased surface expression of calreticulin and depletion of the intracellular HMGB1 protein, indicating its secretion. Thus, such treatment may induce an antitumor immune response, which is supported by the finding in *in vivo* cancer metastasis models that short application of TTFields therapy resulted in a lower rate of metastasis and increased immune infiltration within residual neoplastic lesions [6]. These data have profound clinical implications, as they suggest that combining TTFields therapy with immunotherapy may provide added benefit for cancer patients.

### Distribution of TTFields within the Brain

The NovoTTF-100A device delivers TTFields via two pairs of transducer arrays arranged in an orthogonal fashion on the patient's head (Fig. 3) [42]. Each array consists of 9 ceramic disks connected to a generator and a battery pack. Patients should ideally achieve compliance to treatment of  $\geq 75\%$ , i.e.,  $\geq 18$  h per day.

Computer modeling can provide non-invasive estimation of electric field distribution from the surface arrays on the scalp into various brain structures and into the tumor volume. For this purpose co-registration of MR images and automated or manual segmentation of the different intracranial tissues is performed, known dielectric properties are assigned to each of the segmented tissue types, and ceramic disks from the arrays of the NovoTTF-100A system are placed onto the scalp to build a composite mesh model with various geometries. This model is then imported into finite element modeling software to solve for the electric field distribution, provided that the necessary parameters of tissue dielectric properties are assigned appropriately. The final finite element solution consists of 2-dimensional (2D) plots of the brain shown in axial, coronal, and sagittal planes (Fig. 4).

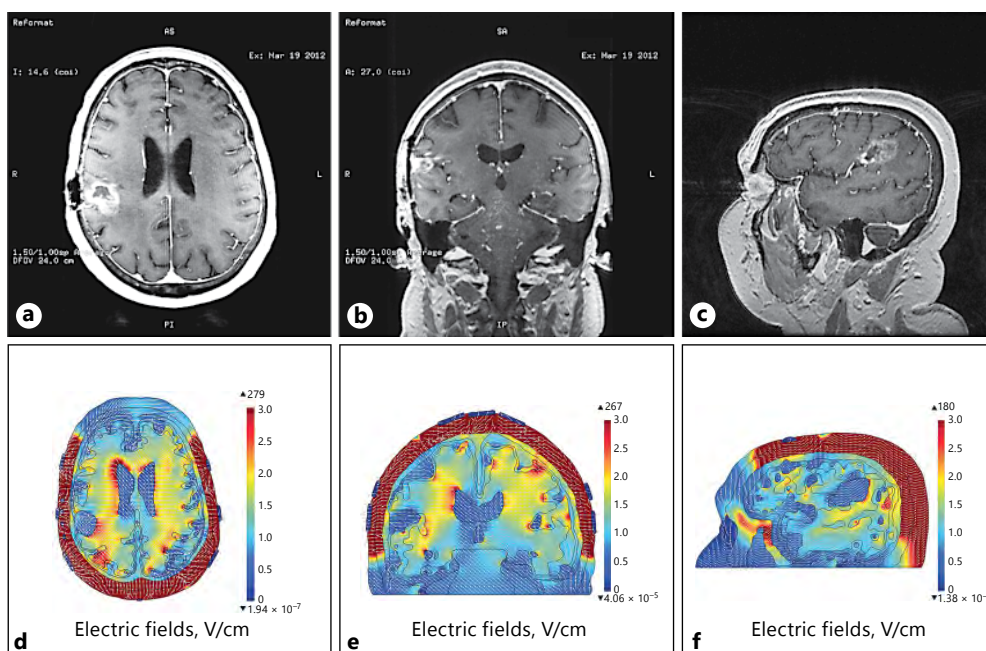

**Fig. 3.** The NovoTTF-100A device consisting of two pairs of orthogonally positioned transducer arrays fixed on the patient's head (courtesy of Aram Boghosian from The Boston Globe).

In concordance with Miranda et al. [43], who used a similar modeling, our group demonstrated inhomogeneous distribution of the induced electric fields throughout the brain [44]. Additionally it was shown that electric fields of higher intensity ( $>3$  V/cm) are located at the interfaces between the cerebrospinal fluid (CSF)-filled spaces (especially, horns of the lateral ventricles) and surrounding tissues [44]. This inhomogeneous distribution may be caused by three possible factors. First, by the relatively large differences in dielectric properties with greater current density in the CSF because fluid is highly conductive. Second, by the differences in the capacitive reactance that oppose changes in electric potential due to the distinct relative permittivity values. Of note, at a constant frequency, the capacitive reactance is inversely proportional to the relative permittivity of tissues. Tissues with lower relative permittivity values exhibit reduced charge retention and thus encounter a lower electric field strength, whereas tissues with higher relative permittivity values may retain larger amounts of charge and will be subjected to a higher electric field intensity. A third factor that may also play a role in the inhomogeneous distribution of TTFields is the specific geometry of the brain, which partially affects the inverse square relationship of the electric field distribution according to Gauss's law. For example, the radial distance between particular sulci and adjacent CSF-filled spaces may vary in different parts of the brain. Nevertheless, further analysis and modeling of TTFields for the treatment of intracranial tumors is definitely needed.

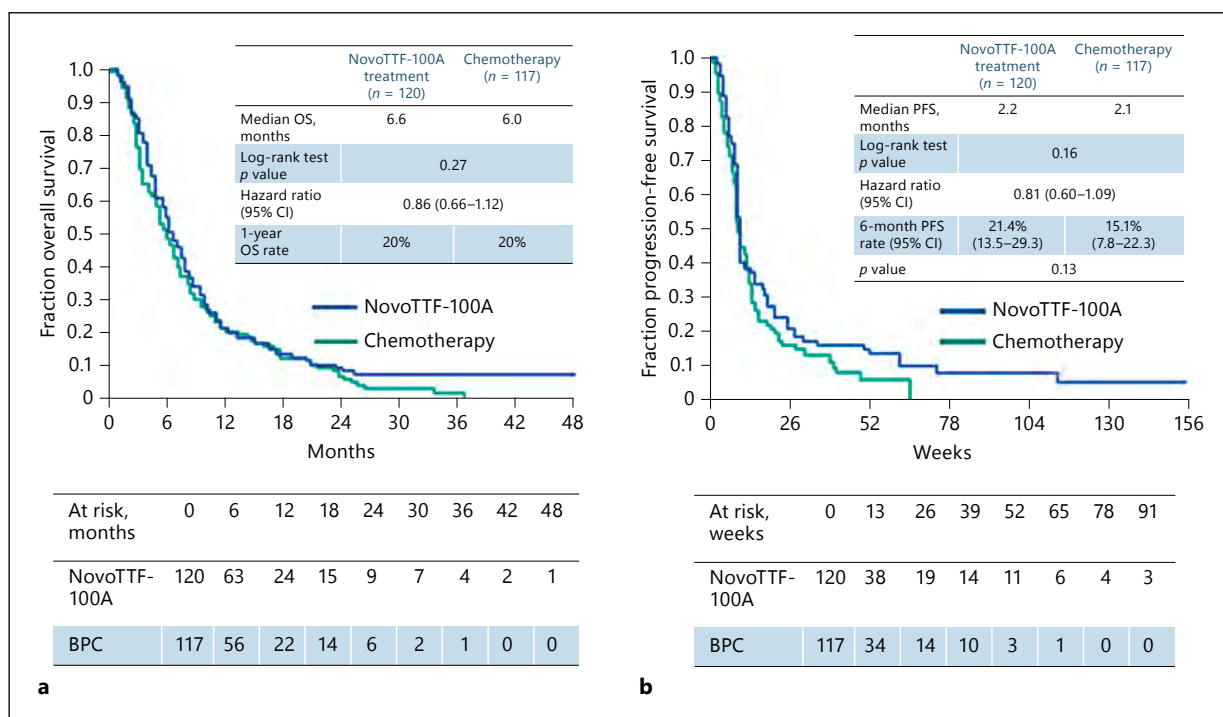

**Fig. 4.** Computer modeling of electric field distribution within the head. Post-contrast T1-weighted MRI in axial (a), coronal (b) and sagittal (c) planes demonstrates recurrent glioblastoma. The electric field distribution was assessed using co-registered post-contrast T1-weighted and T2-weighted images with segmentation of the different intracranial tissues, followed by analysis using finite element modeling software. The final solution is displayed on 2-dimensional plots of the brain in axial (d), coronal (e) and sagittal (f) planes.

### Clinical Results of TTFields Therapy of Intracranial Gliomas

Clinical safety and feasibility of TTFields therapy was initially demonstrated in 10 patients with brain tumors, in one of whom the intracranial electric fields were measured during craniotomy [5]. The median time-to-progression (TTP) of 16.1 weeks (range 3.0–124.0 weeks), overall survival of 62.2 weeks (range 20.3–124.0 weeks), and 1-year survival rate of 67.5% were all favorable in comparison to historical controls [5, 45].

In the pivotal EF-11 phase III study (Table 1) TTFields therapy in patients with recurrent glioblastoma multiforme (GBM) was shown to have comparable efficacy, when compared to the best physician's choice chemotherapy (BPC) that also included bevacizumab (BEV) [8]. There was no obvious hematological and gastrointestinal toxicities. The primary endpoint of this trial was overall survival, which was 6.6 and 6.0 months in patients treated with NovoTTF-100A ( $n = 120$ ) and BPC chemotherapy ( $n = 117$ ), respectively (hazard ratio [HR] 0.86; 95% CI 0.66–1.12;  $p = 0.27$ ). The 1-year survival rate was 20% in both cohorts (Fig. 5). Respective median progression-free survival (PFS) was 2.2 and 2.1 months (HR 0.81; 95% CI 0.60–1.09;  $p = 0.16$ ),

**Fig. 5.** Comparative overall survival (OS [a]) and progression-free survival (PFS [b]) analysis of patients with recurrent glioblastoma according to the prospective randomized EF-11 study demonstrated comparable outcome after TTFields therapy (NovoTTF-100A treatment) and best physician's choice chemotherapy (BPC). From Stupp et al. [8].

whereas 6-month PFS rates were 21.4% (95% CI 13.5–29.3%) and 15.1% (95% CI 7.8–22.3%;  $p = 0.13$ ) [8]. The most common toxicity associated with TTFields therapy was scalp irritation, which was encountered in 14% of patients, but never exceeded grade 2. It could be managed with topical corticosteroids and a slight shift of the arrays during their exchange [46]. The most important advantages associated with the NovoTTF-100A device in comparison to BPC were far fewer instances of grade 2 or greater hematological toxicities (3 vs. 17%) and adverse gastrointestinal events (4 vs. 17%). Quality of life (QOL) analysis demonstrated that patients treated with TTFields therapy had better cognitive and emotional functions than those who received BPC, whereas appetite loss, constipation, diarrhea, fatigue, nausea, vomiting and pain were more often seen in the latter cohort [8]. Based on the comparable efficacy and a lack of serious toxicities, NovoTTF-100A was approved on April 15, 2011 by the FDA for treatment of patients with recurrent GBM.

Clinical characteristics of responders and non-responders to TTFields therapy in the EF-11 cohort were assessed by post hoc analyses [9, 47, 48]. Two characteristics stood out: responders had a higher rate of secondary GBM ( $p = 0.05$ ) and significantly lower dexamethasone usage ( $p < 0.01$ ). Since dexamethasone may cause

immunosuppression in cases of GBM undergoing standard FRT and concomitant TMZ [49], the same effect is most likely imposed onto NovoTTF-100A-treated patients and affects their anticancer immunity [9].

The efficacy of TTFields therapy in clinical practice was analyzed using the Patient Registry Dataset (PRiDe), which included 457 cases of recurrent GBM treated with

NovoTTF-100A across 91 medical centers in the USA [50]. In comparison to the results of the EF-11 trial, more patients in PRiDe received treatment at the time of first tumor recurrence (9 vs. 33%). Median overall survival (9.6 vs. 6.6 months), as well as 1-year (44 vs. 20%), and 2-year (30 vs. 9%) survival rates were greater in PRiDe in comparison to the EF-11 cohort. Initiation of TTFields therapy at the time of first or second recurrence (as compared to third, fourth, or fifth recurrence) and no prior BEV administration were significantly ( $p < 0.01$ ) associated with longer survival (Table 2) [50]. These data further support the benefits of TTFields therapy in cases of recurrent GBM with regard to treatment tolerability, safety, and potential efficacy.

A multicenter EF-14 trial randomized 695 enrolled patients (of preplanned 700) with newly diagnosed GBM after completion of standard FRT concomitant with daily

TMZ in a 2:1 ratio for either adjuvant TTFields therapy combined with TMZ or for adjuvant TMZ alone [51]. The primary endpoint of this study was PFS, and the secondary endpoints were overall survival, 1- and 2-year survival rates, 6-month PFS rate, radiological response, and QOL parameters. In a prespecified interim analysis of the first 315 cases after a minimum follow-up of 18 months (Table 3), the intention-to-treat (ITT) cohort, which received adjuvant TTFields therapy combined with TMZ (*n* = 210) had longer PFS in comparison to those treated with adjuvant TMZ alone (*n* = 105); the median PFS was 7.1 months (95% CI 5.9–8.2 months) vs. 4.0 months (95% CI 3.0–4.3 months), respectively (HR 0.6; *p* = 0.0014) [10]. The overall survival was also longer with adjuvant TTFields therapy combined with TMZ (median survival 19.6 months; 95% CI 16.5–24.1 months vs. 16.6 months; 95% CI 13.5–19.1 months; HR 0.75; *p* = 0.034). The same trend was revealed in the protocol population that started the second cycle of treatment (median survival 20.5 months; 95% CI 16.5–24.1 months; *n* = 196 vs. 15.5 months; 95% CI 13.5–19.1 months; *n* = 84; HR 0.67, *p* = 0.0072). There were no unexpected adverse events, whereas grades 3–4 hematological toxicities (12 vs. 9%), gastrointestinal disorders (5 vs. 2%), and seizures (7 vs. 7%) were similar between the two treatment cohorts. Scalp reactions were more common in patients treated with TTFields (49 vs. 5% for grade 1–2, and 7 vs. 5% for grade 3–4 toxicities) [10]. Thus, preliminary data from the EF-14 study indicate that adjuvant treatment with Novo-TTF-100A combined with TMZ may offer survival advantage in patients with newly diagnosed GBM. A recent 5-year survival analysis of all 695 patients of this trial also showed a sustained benefit of such therapy.

## Conclusion

The evolution of TTFields therapy from the initial laboratory observations of cell membrane blebbing during mitosis to *bona fide* treatment of patients with GBM is an excellent testament to the value of translational neuro-oncology research. Our understanding of the physical attributes, cellular biology effects, and clinical efficacy of TTFields have improved dramatically. Widespread application of this therapeutic

modality in the future will require optimization of treatment regimens by combining TTFields therapy with conventional chemotherapy, FRT, stereotactic radiosurgery, molecular targeted therapy, and/or immunotherapy.

## Policy

Aetna considers devices to generate electric tumor treatment fields (ETTF) medically necessary as monotherapy for persons with histologically confirmed glioblastoma (World Health Organization grade IV astrocytoma), after histologically or radiologically confirmed recurrence in the supratentorial region of the brain after receiving chemotherapy.

Aetna considers combination of devices to generate ETTF and temozolomide medically necessary as adjunctive treatment of newly-diagnosed histologically confirmed supratentorial glioblastoma following standard treatments that include surgery, chemotherapy, and radiation therapy.

Aetna considers devices to generate ETTF experimental and investigational for the treatment of other malignant tumors (e.g., breast, lung, melanoma, ovarian cancer, pancreatic cancer, and solid tumor brain metastases; not an all-inclusive list) and for all other indications because their effectiveness has not been established.

Aetna considers combined ETTF therapy and chemo-immuno-therapy other than temozolomide (e.g., 6-thioguanine, bevacizumab, capecitabine, celecoxib, cisplatin, cyclophosphamide, dacarbazine, doxorubicin, lomustine, paclitaxel, and pemetrexed; not an all-inclusive list) for the treatment of other malignant tumors experimental and investigational because the effectiveness of this approach has not been established.

## Background

Alternating electric fields, generated by insulated electrodes, have been reported to exhibit inhibitory effect on the growth rate of a variety of human and rodent tumor cell lines as well as malignant tumors in animals. This non-thermal effect selectively affects dividing cells while quiescent cells are left intact. There are 2 modes of action for these anti-tumoric effects:

- I. arrest of cell proliferation, and
- II. destruction of cells while undergoing division.
  
- I. arrest of cell proliferation, and
- II. destruction of cells while undergoing division.

Both effects were observed when such fields were applied for 24 hours to cells undergoing mitosis that is oriented along the field direction. The 1st mode of action is manifested by interference with the proper formation of the mitotic spindle, while the 2nd mode of action results in rapid disintegration of the dividing cells. Both effects are consistent with the computed directional forces exerted by these specific fields on charges and dipoles within the dividing

cells. In-vivo treatment of tumors in C57BL/6 and BALB/c mice resulted in significant slowing of tumor growth and extensive destruction of tumor cells within 3 to 6 days. These findings showed the potential applicability of alternating electric fields as a novel therapeutic modality for malignant tumors (Kirson et al, 2004).

Electric tumor treating fields (ETTF), also known as alternating electrical field therapy, are low-intensity (1 to 2 V/cm), intermediate-frequency (100 to 200 kHz), alternating electric fields employed for the treatment of malignant tumors. ETTFs are delivered to a malignant tumor site via insulated electrodes placed around the region of the body containing the tumor. This novel treatment modality has shown promise in pilot clinical trials in patients with advanced stage solid tumors including glioblastoma (GBM).

Kirson et al (2007) reported the findings of a pilot clinical trial examining the effects of ETTF in 10 patients with recurrent GBM. Median time to progression (TTP) in these patients was 26.1 weeks and median overall survival (OS) was 62.2 weeks. The authors noted that these TTP and OS values were more than double the reported medians of historical control patients. No device-related serious adverse events (AEs) were seen after more than 70 months of cumulative treatment in all of the patients. The only device-related AE observed was a mild-to-moderate contact dermatitis beneath the field delivering electrodes. The authors concluded that ETTF are a safe and effective new treatment modality that effectively slows down tumor growth in-vitro, in-vivo, as well as in human cancer patients.

In a pilot study, Salzberg and colleagues (2008) evaluated the safety, tolerability, and effectiveness of ETTF treatment in patients with locally advanced or metastatic solid tumors using the NovoTTF-100A device. A total of 6 patients were heavily pre-treated with several lines of therapy; no additional standard treatment option was available to them. Electric tumor treating fields treatment using continuous NovoTTF-100A lasted a minimum of 14 days and was well-tolerated. No related serious AEs occurred. Outcomes showed 1 partial response of a treated skin metastasis from a primary breast cancer, 3 cases where tumor growth was arrested during treatment, and 1 case of disease progression. One mesothelioma patient experienced lesion regression near ETTF with simultaneous tumor stability or progression in distal areas. The authors concluded that although the number of patients in this study was small, the lack of therapy toxicity and the effectiveness observed in data gathered to date indicate the potential of ETTF as a new treatment modality for solid tumors, thus, warranting further investigation.

Recent reviews indicated the ETTF is a promising approach for the treatment of GBM and non-small cell lung cancer. Stupp and Weller (2010) noted that novel treatment approaches in recurrent GBM include anti-angiogenic agents (e.g., bevacizumab and cilengitide) as well as ETTF (NovoTTF). Furthermore, Pless and Weinberg (2011) reviewed in-vitro and in-vivo pre-clinical studies, showing the activity of ETTF both as a monotherapy as well as in combination with several cytotoxic agents. They also summarized the clinical experience with ETTF, mainly in 2 indications:

- I. recurrent GBM: in a prospective randomized phase III trial, ETTF was compared with best standard care (BSC, including chemotherapy): ETTF significantly improved median OS

compared with standard therapy (7.8 versus 6.1 months) for the patients treated per protocol (Stupp et al, 2010; published as an abstract). Importantly, quality-of-life was also better in the ETTF group (Ram et al, 2010);

- II. a phase II study of second-line treatment of non-small cell lung cancer, where ETTF was administered concomitantly with pemetrexed.
- I. recurrent GBM: in a prospective randomized phase III trial, ETTF was compared with best standard care (BSC, including chemotherapy): ETTF significantly improved median OS compared with standard therapy (7.8 versus 6.1 months) for the patients treated per protocol (Stupp et al, 2010; published as an abstract). Importantly, quality-of-life was also better in the ETTF group (Ram et al, 2010);
- II. a phase II study of second-line treatment of non-small cell lung cancer, where ETTF was administered concomitantly with pemetrexed.

This combination resulted in an excellent median OS of 13.8 months (Pless et al, 2010; published as an abstract). Interestingly, the progression-free survival (PFS) within the area of the ETTF was 28 weeks; however, outside the ETTF the PFS was only 22 weeks. This is an important finding because it can be assumed that in the same patient the higher tumor control within the tumor-treating fields (TTFields) area was a specific effect of TTFields. Median OS was 13.8 months and 1-year survival was 57 %; 6 patients (14.6 %) had a radiological partial remission and 16 patients had stable disease (39 %). The authors stated that these results are promising and compare well with matched historical controls treated with pemetrexed alone in second-line treatment. The authors stated that the proof of concept of ETTF has been demonstrated in the pre-clinical setting, and the clinical data seem promising in various tumor types. The side effects of ETTF were minimal and in general consisted of skin reaction to the electrodes. The authors said that there are a number of ways in which ETTF could be further evaluated, for example, in combination with chemotherapy, as a maintenance treatment, or as a salvage therapy if radiotherapy or surgery is not possible. The authors concluded that while more clinical data are clearly needed, ETTF is an emerging and promising novel treatment concept (Pless and Weinberg, 2011).

On April 15, 2011, the Food and Drug Administration (FDA) approved the NovoTTF-100A System (Novocure, Portsmouth, NH) for the treatment of adults with GBM that recurs or progresses after receiving chemotherapy and radiation therapy. The NovoTTF-100A System is not intended to be used in combination with other cancer treatments. It should only be used after other treatments have failed. The FDA-approved indication for use is: "The NovoTTF-100A System is intended as treatment for adult patients (22 years of age or older) with histologically confirmed glioblastoma multiforme (GBM), following histologically or radiologically confirmed recurrence in the supra-tentorial region of the brain after receiving chemotherapy. The device is intended to be used as a monotherapy, and is intended as an alternative to standard medical therapy for GBM after surgical and radiation options have been exhausted."

The approval was based on data presented to the FDA from a multi-national, randomized, controlled study. The expedited pre-market approval (PMA) includes a requirement for a post-market non-randomized, unblinded, concurrent control study of NovoTTF-100A in patients with recurrent GBM. The primary question to be addressed by the study (FDA, 2011): "Is the overall

survival of patients treated with NovoTTF-100A non-inferior to the survival of patients treated with the best standard of care (chemotherapy)"?

The first randomized clinical study of ETTF did not reach its primary end-point of improved survival compared to active chemotherapy (Stupp et al, 2012; Novocure, 2012). This study was funded and sponsored by the device manufacturer, Novocure, Ltd. Subjects for this study were age 18 years or older with histologically confirmed glioblastoma (World Health Organization grade IV astrocytoma) with radiologically confirmed disease progression. Patients had a Karnofsky performance status greater than or equal to 70 %, and adequate hematologic, renal and hepatic function (absolute neutrophil count greater than or equal to 1,000/mm<sup>3</sup>, hemoglobin greater than or equal to 100 g/L, platelet count greater than or equal to 100,000/mm<sup>3</sup>, serum creatinine level less than or equal to 1.7 mg/dL, total serum bilirubin less than or equal to the upper limit of normal, and liver function values less than 3 times the upper limit of normal. Prior therapy must have included radiotherapy (with and without concomitant and/or adjuvant temozolomide). Patients with infra-tentorial tumor location were excluded, as were patients with implanted electronic medical devices (e.g. pacemaker, programmable ventriculo-peritoneal shunt). Patients were randomized in a 1:1 ratio to receive either NovoTTF-100A without chemotherapy or the physician's choice of active chemotherapy (active control). Chemotherapy agents considered as best standard of care (BSC) during the study included platinum-based chemotherapy (i.e., carboplatin); nitrosureas; procarbazine; combination of procarbazine, lomustine and vincristine; temozolomide; and bevacizumab. For patients assigned to Novo-TTF, uninterrupted treatment was recommended, although patients were allowed to take treatment breaks of up to 1 hour, twice per day, for personal needs (e.g., shower). In addition, patients assigned to Novo-TTF were allowed to take 2 to 3 days off treatment at the end of each of 4 week (which is the minimal required treatment duration for TTF therapy to reverse tumor growth). A period of 28 days of treatment with ETTF was considered 1 full treatment course. The primary end-point of the study was OS. Secondary end-points included PFS rates at 6-months; median time to progression (TTP), 1-year survival rate; quality-of-life; and radiological response. Subjects were seen in clinic monthly, and magnetic resonance imaging (MRI) was performed after 2, 4 and 6 months from initiation of treatment and subsequent MRIs were done according to local practice until disease progression. Medical follow-up continued for 2 months after disease progression. Monthly telephone interviews with the subjects' caregivers were used to evaluate subject mortality rates. A total of 28 clinical centers enrolled 237 adult subjects with 120 subjects randomized to the NovoTTF treatment group and 117 subjects randomized to the BSC group. A total of 30 subjects never started on trial (4 in the treatment group and 26 in the BSC group); 207 subjects started on trial, with 79 % discontinuation rate (n = 47 deaths; n = 49 deterioration of condition; and n = 68 study requirements of 2 additional clinic visits after disease progression were completed). Consent was withdrawn before completing 2 months of post-progression follow-up in 20 subjects. Adverse events led to 20 additional subject withdrawals. Non-compliance with follow-up was attributed to 3 subjects. The proportions were similar between the NovoTTF-100A group and the BSC group of subjects who did not complete the protocol-defined follow-up due to withdrawal of consent, non-compliance, or AEs. An average of 4.2 months of TTF treatment per subject was completed for the 116 subjects in the active treatment cohort. Complete vital statistics were known for 93 % (221 subjects) at the end of the study. There were 202 known deaths and 19 subjects (ETTF =

9; BSC = 10) were still alive 6 months after the last subject was randomized; 16 (7 %) subjects were lost to follow-up.

The trial did not reach its primary end-point of improved survival compared to active chemotherapy (Stupp et al, 2011; Novocure, 2012). In addition, differences in response rates, PFS at 6 months, and reduction in risk of death were not statistically significant. Quality of life analyses favored ETTF therapy in most domains. The differences in median OS between patients in the NovoTTF-100A group and the BSC group were not statistically significant. According to the FDA, the median OS is 6.3 months (95 % confidence interval [CI]: 5.6 to 7.8) in the NovoTTF-100A group and 6.4 months (95 % CI: 5.2 to 7.4) in the BSC group (log rank  $p = 0.98$ ; Wilcoxon  $p = 0.72$ ). The hazard ratio (HR) is 1.0 (95 % CI: 0.76 to 1.32) (test for proportional hazards  $p = 0.45$ ). In the active chemotherapy control arm of the trial, survival was not significantly affected by the choice of chemotherapy. The Kaplan-Meier survival curve for the 2 treatment groups appeared to be very similar during the first 12 months of follow-up. Between 12 and 24 months, the survival curves separated slightly in favor of the BSC control group. There were no statistically significant differences in secondary end-points of 1-year survival, PFS, radiologic response rates, and median TTP. Mild-to-moderate (grade 1 and 2) contact dermatitis on the scalp beneath the transducer arrays occurred in 16 % of ETTF patients. Patients receiving active control chemotherapy experienced toxicity related to pharmacologic mechanism of the agents used: gastrointestinal (30 % versus 8 %), hematological (19 % versus 4 %) and infectious (12 % versus 4 %). Longitudinal Quality of Life (QOL) was available in only 27 % of subjects (63 patients) who remained on study therapy for 3 months and for whom QOL data were available. In the domains of global health and social functioning, no meaningful differences between chemotherapy and ETTF were observed. However, cognitive, emotional, and role functioning favored ETTF, whereas physical functioning favored chemotherapy. Symptom scale analysis is in accordance to treatment-associated toxicity; appetite loss, diarrhea, constipation, nausea and vomiting were directly related to the chemotherapy administration. Increased pain and fatigue was reported in the chemotherapy-treated patients and not in the ETTF treatment group.

Commenting on the trial by Stupp et al, Debonis et al (2012) stated that the study was designed for superiority; although well conducted, it might not have shown it for a limited compliance in the ETTF group. Debonis et al (2012) stated that, even with this limitation, the trial by Stupp et al has shown at least equivalence of ETTF to chemotherapy, with a decreased toxicity and increased quality of life favoring ETTF.

The manufacturer initiated a subsequent randomized clinical trial enrolling newly diagnosed glioblastoma patients after completion of standard radiochemotherapy, parallel to starting the adjuvant or maintenance temozolomide chemotherapy (Stupp et al, 2012). Patients randomized to the experimental arm received ETTF in addition to maintenance temozolomide. In an abstract, Stupp et al (2014) reported on an interim analysis of this international, multi-center, prospective, randomized phase III trial in newly diagnosed GBM patients. After completion of radiotherapy (RT) with concomitant temozolomide (TMZ), patients were randomized (2:1) to adjuvant TMZ with NovoTTF or adjuvant TMZ alone. The primary end-point was PFS, with OS an important secondary end-point. Analysis was by intention-to-treat. The investigators reported on a pre-specified interim analysis of the first 315 patients randomized, after a

minimum follow-up of 18 months (range of 18 to 60 months). Investigators randomized 210 patients NovoTTF/TMZ and 105 to TMZ alone. Patient characteristics were balanced: median age of 57 and 58 years, tumor resection in 89 and 90 %, KPS 90 %, for the NovoTTF and the control arms, respectively. MGMT promoter methylation status was assessable centrally in 60 % of patients; of these 39 % and 41 % were methylated. Adverse events (AE) were comparable between treatment arms. The most common device-related AE was skin irritation in 45 % of patients (all grades, severe 2 %). Severe seizures were observed at a frequency of 7 % in both arms. Median PFS was 7.1 months [mo] (95 % CI: 5.9 to 8.2) and 4.0 mo (CI: 3.0 to 4.3; HR 0.63,  $p = 0.001$ ), OS was 19.6 mo (CI: 16.5 to 24.1) and 16.6 mo (CI: 13.5 to 19.1) (HR 0.75,  $p = 0.034$ ), both favoring NovoTTF. This translated into a 24-mo survival rate of 43 % (CI: 36 to 50 %) and 29 % (CI: 21 to 39 %) for the NovoTTF/TMZ and the TMZ alone arm, respectively. The investigators stated that the trial met its primary and main secondary end-points, and was closed to accrual after this interim analysis. The investigators concluded that adjuvant TMZ chemotherapy and NovoTTF provided a clinically and statistically significant improvement in PFS and OS, and should become the new standard of care against GBM.

The National Comprehensive Cancer Network (NCCN, 2013) had a Category 2B recommendation to consider the use of ETTF for persons with local, diffuse or multiple recurrences of glioblastoma. This was changed to a Category 3 recommendation in 2014 (NCCN, 2014). NCCN guidelines explain that approval of tumor treating fields (TTF) for recurrent glioblastoma was based on results of a clinical trial that randomized 237 patients to TTF or chemotherapy. Similar survival was observed in the 2 arms, and TTF therapy was associated with lower toxicity and improved quality of life. Due to the lack of efficacy, not all NCCN panelists recommended the treatment. This was subsequently changed to a category 2B recommendation in 2015 (NCCN, 2015).

Medicare Durable Medical Equipment Medicare Administrative Contractor (DME MAC) considers tumor treatment field therapy not reasonable and necessary for Medicare beneficiaries (NHIC, 2014).

On October 5, 2015, the FDA approved an expanded indication for the Optune device (using alternating electrical fields called “tumor treatment fields” [TTFields]) to treat patients with newly-diagnosed GBM. It is administered along with temozolomide (TMZ) following standard treatments that include surgery, chemotherapy, and radiation therapy. In the clinical study used to support the expanded indication, patients treated with the device and TMZ lived on average 3 months longer than those treated with the drug alone. Optune was initially approved in 2011 to treat patients with GBM that recurred or progressed after chemotherapy. With this expanded indication, Optune can be used as part of a standard treatment for GBM before the disease progresses. For newly diagnosed GBM, Optune is not intended to be used as a substitute for standard treatments, but rather as an adjunct therapy. The device is portable and can be powered with batteries or plugged into an electrical outlet. Patients can use the device at home or work, allowing them to continue their normal daily activities.

The FDA based its approval of the expanded indication of the Optune device on results from a clinical trial involving 695 patients newly diagnosed with GBM that compared those who used

Optune with TMZ to those receiving TMZ alone. Patients who used the device along with TMZ lived, on average, about 7 months with no disease progression compared to 4 months for those who had the drug alone. The Optune plus TMZ group survived for an average of 19.4 months after diagnosis compared to 16.6 months for those who were treated with only TMZ. The most common side effect experienced with Optune was skin irritation. Clinical trial participants also experienced a slightly higher incidence of neurological side effects, including convulsions and headaches, compared to subjects receiving TMZ alone. Patients should not use the Optune system if they have an active implanted medical device or a skull defect, have an underlying skin condition involving the scalp or have a known sensitivity to conductive hydrogels, such as those used on electrocardiogram stickers.

Electric tumor treating fields technology is also being studied as a treatment for other solid tumors (e.g., melanoma and non-small cell lung cancer). However, there is a paucity of published evidence from randomized controlled trials examining the long-term safety and effectiveness of ETTF as a treatment of tumors.

Davis et al (2013) stated that TTFields therapy has been demonstrated in multiple cell lines when the appropriate frequency was utilized. A phase III trial of TTFields monotherapy compared to active chemotherapy in recurrent glioblastoma patients established that TTFields therapy is associated with minimal toxicity, better quality of life, and comparable efficacy to chemotherapy. Ongoing and future trials will evaluate TTFields in newly diagnosed glioblastoma, solid tumor brain metastases, non-small cell lung cancer, and ovarian and pancreatic cancers.

The NovoTAL System is a workstation-based software tool that uses MRI head morphology, tumor size and location measurements, and tissue di-electric properties to optimize TTFields distribution and intensity within the brain tumor. This system is part of the NovoTTF electronic tumor treatment fields treatments used for the treatment of GBM.

## **Melanoma:**

Li and colleagues (2016) proposed a method of using electrical stimulation for treatment of malignant melanoma through directly spray-printing liquid metal on skin as soft electrodes to deliver low intensity, intermediate frequency electric fields. With patterned conductive liquid metal components on mice skin and under assistance of a signal generator, a sine wave electrical power with voltage of 5 V and 300 kHz could be administrated on treating malignant melanoma tumor. The experiments demonstrated that tumor volume was significantly reduced compared with that of the control group. Under the designed parameters (signal: sine wave, signal amplitude  $V_{pp}$ : 5 V and  $V_{pp}$ : 4 V, frequency: 300 kHz) of Tumor treating fields (TTFields) with the sprayed liquid metal electrode, 4 mice tumor groups became diminishing after 1 week of treatment. The only device-related side effect as seen was a mild-to-moderate contact dermatitis underneath the field delivering electrodes. The scanning electron microscope (SEM) images and pathological analysis demonstrated the targeted treating behavior of the malignant melanoma tumor. Further, thermal infrared imaging experiments indicated that there was no evidence of heating effects in the course of treatment. Besides, the liquid metal was easy to remove through

medical alcohol. The authors concluded that tumor treating fields through liquid metal electrode could offer a safe, straightforward and effective treatment modality that slowed down tumor growth *i- vivo*. They stated that these promising results also raised the possibility of applying spray-printing TTFields as an easy going physical way for future cancer therapy.

### **Combination of ETTF and Chemo-Immuno-Therapy for Other Malignant Tumors:**

In a pilot, in-vitro and in-vivo, clinical trial, Kirson et al (2009) examined the effectiveness and toxicity of combining TTFields with chemotherapeutic treatment. Cell proliferation in culture was studied in human breast carcinoma (MDA-MB-231) and human glioma (U-118) cell lines, exposed to TTFields, paclitaxel, doxorubicin, cyclophosphamide and dacarbazine (DTIC) separately and in combinations. In addition, these researchers studied the effects of combining chemotherapy with TTFields in an animal tumor model and in a pilot clinical trial in recurrent and newly diagnosed GBM patients. The effectiveness of TTFields-chemotherapy combination in-vitro was found to be additive with a tendency towards synergism for all drugs and cell lines tested (combination index less than or equal to 1). The sensitivity to chemotherapeutic treatment was increased by 1 to 3 orders of magnitude by adjuvant TTFields therapy (dose reduction indexes 23 to 1,316). Similar findings were seen in an animal tumor model. Finally, 20 GBM patients were treated with TTFields for a median duration of 1 year. No TTFields-related systemic toxicity was observed in any of these patients, nor was an increase in temozolomide toxicity seen in patients receiving combined treatment. In newly diagnosed GBM patients, combining TTFields with temozolomide treatment led to a PFS of 155 weeks and OS of 39+ months. The authors concluded that these results indicated that combining chemotherapeutic cancer treatment with TTFields may increase chemotherapeutic effectiveness and sensitivity without increasing treatment related toxicity.

Pless et al (2013) noted that TTFields exhibit anti-mitotic activity in cancer cells, and promising pre-clinical data have led to a single-arm phase I/II clinical trial in patients with non-small cell lung cancer (NSCLC). A total of 42 inoperable stage IIIB (with pleural effusion) and stage IV NSCLC patients who had had tumor progression received intravenous pemetrexed 500 mg/m<sup>2</sup> q3w together with daily TTFields therapy until disease progression. The primary end-point was time to "in-field" progression. Median age for all patients was 63 years, 76 % had stage IV disease, 78 % had adenocarcinoma and 17 % had performance status of 2. The median time to in-field progression was 28 weeks and the median time to systemic progression was 22 weeks. Six patients (14.6 %) had a partial remission (PR) and 20 had stable disease (SD) (48.8 %). Median OS was 13.8 months and 1 year survival rate was 57 %. There were no TTFields-related serious adverse events. The authors concluded that the combination of TTFields and pemetrexed as a second-line therapy for NSCLC is safe and potentially more effective than pemetrexed alone. They stated that TTFields improved disease control within the treatment field and a phase III study is planned to further investigate its role as a novel treatment in NSCLC.

Giladi et al (2014) stated that NSCLC is one of the leading causes of cancer-related deaths worldwide. Common treatment modalities for NSCLC include surgery, radiotherapy, chemotherapy, and, in recent years, the clinical management paradigm has evolved with the advent of targeted therapies. Despite such advances, the impact of systemic therapies for

advanced disease remains modest, and as such, the prognosis for patients with NSCLC remains poor. Standard modalities are not without their respective toxicities and there is a clear need to improve both safety and effectiveness for current management approaches. Tumor-treating fields are low-intensity, intermediate-frequency alternating electric fields that disrupt proper spindle microtubule arrangement, thereby leading to mitotic arrest and ultimately to cell death. These researchers evaluated the effects of combining TTFields with standard chemotherapeutic agents on several NSCLC cell lines, both in-vitro and in-vivo. Frequency titration curves demonstrated that the inhibitory effects of TTFields were maximal at 150 kHz for all NSCLC cell lines tested, and that the addition of TTFields to chemotherapy resulted in enhanced treatment efficacy across all cell lines. They investigated the response of Lewis lung carcinoma and KLN205 squamous cell carcinoma in mice treated with TTFields in combination with pemetrexed, cisplatin, or paclitaxel and compared these to the efficacy observed in mice exposed only to the single agents. Combining TTFields with these therapeutic agents enhanced treatment efficacy in comparison with the respective single agents and control groups in all animal models. The authors concluded that these findings suggested that combining TTFields therapy with chemotherapy may provide an additive efficacy benefit in the management of NSCLC. They stated that further prospective studies to examine the optimal combinations of therapy are needed.

Omar (2014) stated that prior to the approval of the TTF System, the only FDA approved treatment for recurrent GBM (rGBM) was bevacizumab. By blocking the VEGF pathway, bevacizumab can result in a significant radiographic response (pseudo-response), improve PFS and reduce corticosteroid requirements in rGBM patients. Bevacizumab however failed to prolong OS in a recent phase III trial. A pivotal phase III trial (EF-11) demonstrated comparable OS between physicians' choice chemotherapy and TTF Therapy but better quality of life were observed in the TTF arm. There is currently an unmet need to develop novel approaches designed to prolong OS and/or improve quality of life in this unfortunate patient population. One appealing approach would be to combine the 2 currently approved treatment modalities namely bevacizumab and TTF Therapy. These 2 treatments are currently approved as monotherapy, but their combination has never been evaluated in a clinical trial.

Wong et al (2015) treated a series of patients with NovoTTF-100A and bevacizumab alone (n = 34) or in combination with a regimen consisting of 6-thioguanine, lomustine, capecitabine, and celecoxib (TCCC) (n = 3). Compared to the former cohort, the latter cohort exhibited a trend for prolonged OS, median of 4.1 (0.3 to 22.7) months versus 10.3 (7.7 to 13.6) months, respectively (p = 0.0951), with 1 experiencing an objective response with a 50 % reduction in tumor size on MRI despite possessing a larger tumor size at baseline and more severe neurologic dysfunction than the median for either group. These preliminary observations illustrated the possibility of improving survival and achieving a response in patients with end-stage recurrent glioblastoma by biasing the tumor toward anti-tumor immunologic response with a combination of NovoTTF-100A and TCCC, as well as the continuation of bevacizumab in order to limit dexamethasone use due to its global immunosuppressive effect on the patient.

**Table: CPT Codes / HCPCS Codes / ICD-10 Codes**

*Information in the [brackets] below has been added for clarification purposes. Codes requiring a 7th character are represented by "+":*

*Information in the [brackets] below has been added for clarification purposes. Codes requiring a 7th character are represented by "+":*

Code	Code Description
<b>ICD-hyphen10 codes will become effective as of October 1, 2015:</b>	
<b>HCPCS codes covered if selection criteria are met:</b>	
<b>A4555</b>	Electrode/transducer for use with electrical stimulation device used for cancer treatment, replacement only
<b>E0766</b>	Electrical stimulation device used for cancer treatment, includes all accessories, any type
<b>J8700</b>	Temozolomide, oral, 5 mg
<b>J9328</b>	Injection, temozolomide, 1 mg
<b>ICD-hyphen10 codes covered if selection criteria are met:</b>	
<b>C71.0 -hyphen C71.9</b>	Malignant neoplasm of brain [supratentorial glioblastomas (WHO grade IV astrocytomas)]
<b>ICD-hyphen10 codes not covered for indications listed in the CPB (not all inclusive):</b>	
<b>C11.0 -hyphen C11.9</b>	Malignant neoplasm of nasopharynx
<b>C15.3 -hyphen C15.9</b>	Malignant neoplasm of esophagus
<b>C16.0 -hyphen C16.9</b>	Malignant neoplasm of stomach
<b>C18.0 -hyphen C18.9</b>	Malignant neoplasm of colon
<b>C19 -hyphen C21.8</b>	Malignant neoplasm of rectosigmoid junction, rectum, anus and anal canal
<b>C22.1</b>	Intrahepatic bile duct carcinoma
<b>C23 -hyphen C24.9</b>	Malignant neoplasm of gall bladder and other and unspecified parts of biliary tract

## Medical Policy Bulletin

Title: **Tumor Treating Fields**

Policy #: **07.03.26**

The below medical or claim payment policy is applicable to the Company's commercial products only. Policies that are applicable to the Company's Medicare Advantage products are accessible via a separate [Medicare Advantage policy database](#).

The Company makes decisions on coverage based on Policy Bulletins, benefit plan documents, and the member's medical history and condition. Benefits may vary based on contract, and individual member benefits must be verified. The Company determines medical necessity only if the benefit exists and no contract exclusions are applicable.

When services can be administered in various settings, the Company reserves the right to reimburse only those services that are furnished in the most appropriate and cost-effective setting that is appropriate to the member's medical needs and condition. This decision is based on the member's current medical condition and any required monitoring or additional services that may coincide with the delivery of this service.

This Medical Policy Bulletin document describes the status of medical technology at the time the document was developed. Since that time, new technology may have emerged or new medical literature may have been published. This Medical Policy Bulletin will be reviewed regularly and be updated as scientific and medical literature becomes available. For more information on how Medical Policy Bulletins are developed, go to the About This Site section of this Medical Policy Web site.

### Policy

Coverage is subject to the terms, conditions, and limitations of the member's contract.

#### MEDICALLY NECESSARY

NEWLY DIAGNOSED GLIOBLASTOMA WHEN USED IN ADJUVANT TREATMENT  
Alternating **electric** tumor treating **fields** (TTFields) are medically necessary and, therefore, covered for adult individuals (22 years of age or older) with newly diagnosed glioblastoma, when the individual meets all of the following criteria:

- Histologically confirmed glioblastoma (World Health Organization grade IV astrocytoma)
- Tumor located in the supra-tentorial region of the brain
- Karnofsky Performance Score above 60
- Completed standard therapeutic options, such as maximum safe debulking surgery, concomitant temozolomide, or radiotherapy
- TTFields is prescribed with adjuvant temozolomide (maintenance)
- Willingness to use the TTFields device daily for at least 18 hours

RECURRENT GLIOBLASTOMA WHEN USED AS A MONOTHERAPY  
Alternating **electric** TTFields are medically necessary and, therefore, covered when used as a monotherapy for adult individuals (22 years of age or older) with recurrent glioblastoma, when the individual meets all of the following criteria:

- Histologically confirmed glioblastoma (World Health Organization grade IV astrocytoma)
- Tumor located in the supra-tentorial region of the brain
- Karnofsky Performance Score above 60
- Completed standard therapeutic options, such as maximum safe debulking surgery or systemic chemotherapy or irradiation
- Willingness to use the TTFields device daily for at least 18 hours

#### NOT MEDICALLY NECESSARY

TTFields are considered not medically necessary and, therefore, not covered because the available published peer-reviewed literature does not support their use for the treatment of individuals with glioblastoma who have any of the following: an implanted pacemaker, programmable shunts, defibrillator, deep brain stimulator, other implanted devices in the brain, documented clinically significant arrhythmias, or evidence of increased intracranial pressure.

EXPERIMENTAL/INVESTIGATIONAL

All other uses of TTFields are considered experimental/investigational and, therefore, not covered because their safety and/or effectiveness cannot be established by review of the available published peer-reviewed literature.

REQUIRED DOCUMENTATION

The Company may conduct reviews and audits of services to our members regardless of the participation status of the provider. Medical record documentation must be maintained on file to reflect the medical necessity of the care and services provided. These medical records may include but are not limited to: records from the professional provider's office, hospital, nursing home, home health agencies, therapies, and test reports.

PRESCRIPTION (ORDER) REQUIREMENTS

Before submitting a claim to the Company, the supplier must have on file a timely, appropriate, and complete order for each item billed that is signed and dated by the professional provider who is treating the member. Requesting a provider to sign a retrospective order at the time of an audit or after an audit for submission as an original order, reorder, or updated order will not satisfy the requirement to maintain a timely professional provider order on file.

PROOF OF DELIVERY

Medical record documentation must include a contemporaneously prepared delivery confirmation or member's receipt of supplies and equipment. The medical record documentation must include a copy of delivery confirmation if delivered by a commercial carrier and a signed copy of delivery confirmation by member/caregiver if delivered by the DME supplier/provider. All documentation is to be prepared contemporaneous with delivery and be available to the Company upon request.

CONSUMABLE SUPPLIES (WHEN APPLICABLE)

The durable medical equipment (DME) supplier must monitor the quantity of accessories and supplies an individual is actually using. Contacting the individual regarding replenishment of supplies should not be done earlier than approximately seven days prior to the delivery/shipping date. Dated documentation of this contact with the individual is required in the individual's medical record. Delivery of the supplies should not be done earlier than approximately five days before the individual would exhaust their on-hand supply.

If required documentation is not available on file to support a claim at the time of an audit or record request, the durable medical equipment (DME) supplier may be required to reimburse the Company for overpayments.

Guidelines

Tumor treating **fields** (TTFields) for the treatment of newly diagnosed and/or recurrent glioblastoma (GBM) utilizes a portable battery or power supply operated device which produces alternating **electrical fields** within the human body. TTFields are applied to individuals by **electrically** insulated surface transducer arrays. TTFields disrupt the rapid cell division exhibited by cancer cells.

TTFields are intended to harness **electric fields** to arrest the proliferation of tumor cells and to destroy them. The TTFields technology takes advantage of the special characteristics and geometrical shape of dividing cells, which make them susceptible to inhibiting cellular division during mitosis. The **fields** are said to alter the tumor cell polarity at an intermediate frequency (on the order of 100-300 kHz). The frequency used in the treatment of GMB has been specified to 200kHz.

KARNOFSKY PERFORMANCE STATUS (KPS)

A scale measuring the ability of individuals to perform ordinary tasks. KPS scores range from 0 to 100; a higher score means a person is better able to carry out daily activities.

KPS	Definition
100	Normal; no complaint; no evidence of disease
90	Able to carry on normal activity; minor signs of symptoms of disease
80	Normal activity with effort; some sign or symptoms of disease
70	Cares for self; unable to carry on normal activity of do active work
60	Requires occasional assistance, but is able to care for most personal needs
50	Requires considerable assistance and frequent medical care
40	Disabled; requires special care and assistance
30	Severely disabled; hospitalization is indicated, although death not imminent
20	Very sick; hospitalization necessary; active support treatment is necessary
10	Moribund; fatal processes progressing rapidly
0	Dead

NATIONAL COMPREHENSIVE CANCER NETWORK

The National Comprehensive Cancer Network® (NCCN®), a not-for-profit alliance of 27 leading cancer centers devoted to patient care, research, and education, is dedicated to improving the quality, effectiveness, and efficiency of cancer care so that patients can live better lives. NCCN® promotes the importance of continuous quality improvement and recognizes the significance of creating clinical practice guidelines

appropriate for use by patients, clinicians, and other health care decision-makers. NCCN® provides a clinical practice guideline appropriate for use in the treatment of glioblastoma, both as a new diagnosis and in recurrent disease.

NCCN® provide clinical practice guidelines for central nervous system cancers on a variety of prognostic factors, such as: age, good performance status (KPS=60) , MGMT promotor status (methylated or unmethylated/indeterminate). When the medically necessary criteria listed in this medical policy are met, the NCCN® clinical practice guidelines endorse the use of TTFields, as follows:

**IN THE TREATMENT OF NEWLY DIAGNOSED GLIOBLASTOMA**

Maximum resection + carmustine (BCNU) wafer with adjuvant treatments inclusive of standard brain RT (recommended dose is 60 Gy in 2.0 Gy fractions or 59.4 Gy in 1.8 Gy fractions) + concurrent temozolomide and adjuvant temozomide + alternating **electric field therapy**.

**IN THE TREATMENT OF RECURRENT GLIOBLASTOMA**

Resection with or without carmustine (BCNU) wafer AND palliative/best supportive care if poor performance, or systemic chemotherapy, or consider reirradiation (category 2B) or alternating **electric field therapy** for glioblastoma (category 2B).

**REGULATORY STATUS**

On April 8, 2011, the FDA gave premarket approval for the NovoTTF-100A system (NovoCure Inc. Portsmouth, New Hampshire) for the treatment of adult patients (22 years of age or older) with histologically confirmed glioblastoma multiforme (GBM), following histologically or radiologically confirmed recurrence in the supra-tentorial region of the brain after receiving chemotherapy. The device is intended to be used as a monotherapy, and is intended as an alternative to standard medical **therapy** for GBM after surgical and radiation options have been exhausted.

On October 5, 2015, the FDA expanded approval for Optune™ (formerly NovoTTF-100A) system for the treatment of adult patients with newly diagnosed, supra-tentorial glioblastoma following maximal debulking surgery and completion of radiation **therapy** together with concomitant standard of care chemotherapy.

**BENEFIT APPLICATION**

Subject to the terms and conditions of the applicable benefit contract, TTFields are covered as durable medical equipment (DME) under the medical benefits of most of the Company's products when the medical necessity criteria listed in this medical policy are met.

**Description**

Glioblastoma multiforme (GBM) is the most prevalent and most fatal malignant brain tumor in adults, accounting for nearly 15% of all brain cancers. GBMs account for 46.6% of all malignant tumors with 12,150 new cases predicted annually. Malignant gliomas are histologically heterogeneous and invasive tumors that are derived from neuroglia, or glial cells, whose primary responsibility is to support the central nervous system's neuron cells. GBMs are classified by the World Health Organization (WHO) as astrocytoma. The WHO provides a grading scale based on the most malignant regions of the tumors. Tumor grades depend upon degree of nuclear atypia, mitotic activity, microvascular proliferation, and necrosis, with increased anaplasia, corresponding to higher tumor grades. The 2007 WHO classification of GBM is a grade IV, indicating the most severe cancer grade, exhibiting rapid tumor growth leading to exceedingly poor prognosis. Eighty percent of individuals diagnosed with GBM will progress to recurrent disease, even after the initial surgical options have been exhausted. Survival expectancy for individuals with newly diagnosed GBM averages between 14.6 to 16.7 months with one-year survival rates of 35%. Following a GBM recurrence, the one-year survival rate is only approximately 20%, and median survival ranges from three to nine months.

Although the prognosis is dismal, the treatment options remain limited. The standard first-line treatment for a GBM is maximum surgical resection of the tumor. The National Comprehensive Cancer Network (NCCN®) has developed clinical practice guidance for the treatment of GBM. At present, the recommended treatment for an individual who is newly diagnosed with a histologically confirmed GBM is: maximum resection surgery, followed by radiotherapy (fractionated focal irradiation in daily fractions of 2 Gray [Gy] given 5 days per week for 6 weeks, for a total of 60 Gy). Gray is a unit of measurement for ionized radiation defined by the absorption of one joule of radiation per one kilogram of matter. In addition to radiotherapy, individuals are treated with concomitant continuous daily temozolomide (75 mg per square meter of body-surface area per day, 7 days per week from the first to the last day of radiotherapy), then subsequent cycles (6) of adjuvant temozolomide (150 to 200 mg per square meter for 5 days during each 28-day cycle). For disease recurrence, standard care includes surgical resection in combination with Gliadel® Wafer, stereotactic radiosurgery, and re-operation for additional tumor resection. Irrespective of the varying treatment protocols between the newly diagnosed and recurrent populations, GBM reoccurrence is still 80% and two-year survival rates remain a mere 27% following initial diagnosis. Acknowledging these dismal treatment outcomes, research has been conducted on new therapeutic agents for the treatment of glioblastoma. Stupp et al developed a new technology called tumor treating **fields** (TTFields) initially utilized and studied to treat the population with recurrent GBM disease.

TTFields is a technology utilizing **electric** activity through **fields** and currents to influence the of polarity of molecules, ions, and the cell membranes found in biological organisms to exert an effect on cellular process and impact cell division. By exposing cancer cells to alternating **electric fields** of low intensity and intermediate frequency, cellular polarity and ionic energy could be manipulated. This mechanism of action purported by TTFields (alternating **electric fields**) could selectively arrest cellular division (cytokinesis) in cancer cells by impairing normal mitosis and cytokinesis. TTFields are shown to have no effect on non-dividing cells, but to induce apoptosis in dividing cells. The **electric** ?elds interfere with cell division by causing misalignment of highly polarized subunits (microtubule monomers) in the mitotic spindle during the metaphase to anaphase transition and by dielectrophoretic movement of intracellular macromolecules and organelles during telophase. During cytokinesis, TTFields generate non-uniform intracellular **fields**, pulling organelles towards the neck that separates the newly forming daughter cells. In addition, TTFields interfere with the formation of the mitotic spindle by exerting forces on the charged tubulin subunits. Both processes lead to cell apoptosis and tumor growth inhibition. TTFields exert maximal effects when aligned to a cell's mitotic axis. As a cell's mitotic axis can occur randomly in any direction, additive cytotoxic effects are also observed when TTFields are applied in multiple sequential directions.

Individuals who utilize this technology for the treatment of GBM would need to place four transducer arrays onto their shaved scalp and connected to a portable, battery or power supply operated device (Optune, formerly the NovoTTF-100A system), which is preset to generate 200 kHz **electric fields** within the brain in two sequentially, perpendicular directions. The intensity of the **field** is also preset by the manufacturer at >0.7 V/cm. Treatment is intended to be continuous and take place in the home setting to allow the participants to maintain daily activities. Transducer arrays are supplied sterile, and prior to placement of the arrays, the scalp must be shaved carefully to limit the adverse effects (i.e., skin irritation, skin wounding). Although uninterrupted treatment is recommended, individuals can take treatment breaks of up to an hour, twice per day, for personal needs (i.e., shower).

The electrodes themselves are made from high dielectric constant insulated ceramic discs soldered to a flexible circuit board. The flexible printed circuit incorporates the components required for delivering the current for each ceramic plate and for measuring the temperature. At the set parameters, the electrodes are not reported to cause significant heating due to dielectric losses of the insulation or induced **fields** in the target tissue.

The Optune system contains a separate software component for the use of clinical treatment planning. The NovoTAL™ system is a workstation based software tool that uses MRI head morphology, tumor size and location measurements, and tissue dielectric properties to optimize the TTFields' distribution and intensity within the tumor by determining the specific region of the brain to treat with the placement of paired arrays. The planning software is intended for use by physicians certified to prescribe electronic TTFields used for the treatment of GBM.

PEER REVIEWED LITERATURE

Kirson et al (2004) evaluated 11 types of cancerous cell lines in more than 500 in vitro culture dishes. The researchers calculated growth rates of the cells and measured cell proliferation. In all cell lines reviewed, each culture dish was exposed to TTFields for a period of 24-hour intervals at 100 kHz (at an intensity of 1.0–1.4 V/cm), which resulted in significant inhibition of cell proliferation. To test the relationship between TTFields' intensity and inhibition of cell proliferation, Kirson et al exposed mouse melanoma and rat glioma cell lines to TTFields of different intensities between 1 and 2.5 V/cm. Furthermore, authors reported that the inhibitory effect of TTFields on cell proliferation increased as intensity increased until complete proliferation arrest was achieved at intensities of 1.4 and 2.25 V/cm in melanoma and glioma cells, respectively. The authors reported on the most relevant findings regarding the prolongation of mitosis, stating in treated cells, mitosis seemed to begin normally but was prolonged for variable periods of time before completing cleavage into two daughter cells. In the 500 cells evaluated, the authors reported TTFields had exemplary effect on the cellular process. In the cells treated with TTFields, mitosis was not complete within the standard 3 hours. TTFields treated cells displayed proliferation arrest, and mitosis lasted on average  $124 \pm 91$  min (mean Standard Deviation [SD], n= 53; 40–541 min), whereas in the controlled cells, the average mitosis duration was  $62 \pm 8$  min from cell rounding to cytokinesis with a mean SD of 12 and a range of 47-78 minutes. Their findings resulted in statistically significant prolongation of mitosis ( $P < 0.01$ , Mann-Whitney U test).

The authors reported in vivo studies with two animal tumor models. TTFields were generated between implanted (intradermal) wholly insulated wires placed on both sides of the tumor. The researchers placed two sets of paired identical insulated wires on the back of a mouse. The comparative in the mouse study was that only one of the pairs were connected to device, thus only exposing the area under the connected pair to TTFields treatment.

The researchers demonstrated that 100 KHz to 1 MHz alternating direction **fields** have significant specific effects on dividing cells. They reported that the areas treated with **electric field** of alternating direction provided evidence that all charges and polar molecules are subjected to forces of alternating direction so that ionic flows and dipole rotation oscillate. The basis of these effects during cytokinesis was shown to be that the unidirectional forces induced by disrupting mitotic spindle formation could result in physical disruption of the cell membrane and ultimately to apoptosis. During mitosis, exposure of cells to those **fields** results in one-fourth being destroyed as the formation of the cleavage furrow approached complete cell separation and violent membrane protrusions and cells exhibit disruption of microtubule spindle elements. Additionally, the authors reported that the direction of the placed **electrical** current dictates the magnitude of cellular disruption. Kirson et al concluded that when TTFields are placed parallel to the plane division, cells exhibited more mitotic failure. Placement of the TTFields arrays is an important instruction when the technology is indicated in the treatment of cancers.

TUMOR TREATING **FIELDS** FOR THE TREATMENT OF RECURRENT, SUPRA-TENTORIAL GLIOBLASTOMA MULTIFORME

Kirson et al 2007 evaluated a single arm, pilot trial study on the safety and efficacy of TTFields treatment that was performed on 10 participants with recurrent GBM. Efficacy analysis was performed for recurrent GBM persons focusing on time to disease progression (TTP), progression-free survival at 6 months (PFS6), and overall survival (OS) as the primary outcomes for individuals treated with the NovoTTF-100A device. Based on such a small sample size no statistical hypothesis tests were measured. This study measured progression-free survival at 6 months (PFS6), producing a result of 50% (23–77%; 95% confidence interval). Ninety-five percent confidence intervals of survival proportions were calculated using Kaplan–Meier survival curves. The initial pilot study reported two of the ten participants surviving beyond the follow-up period, with the longest participant living for 124.0 weeks, differing from historical averages.

The authored indicated that the pilot study demonstrated TTP and OS values that were more than double the reported historical medians, and reported that TTFields treatment resulted in one complete response which was tumor free, confirmed by MRI ten months after stopping treatment, and one partial response which was still responding seven months after stopping treatment. Both were still progression free two years from treatment initiation. In addition, one participant had minimal response, and four had stable disease for over 4 months before progressing, with the authors suggesting that the device could conceivably halt tumor growth.

The seminal trial, which led to the Food and Drug Administration (FDA) granting approval of TTFields, was a prospective randomized, phase III trial (EF-11) conducted by Stupp et al. (2012). The EF-11 trial assessed TTFields as a monotherapy, without chemotherapy, compared to physician's standard chemotherapy. 237 participants were randomly assigned in a 1:1 ratio to receive either TTFields, (n=120) or an active control entailing the best available chemotherapy prescribed at the local investigator's discretion (n= 117). Participants were all at least 24 years old, with an average age of 54, had Karnofsky performance scores of = 70 with limited other comorbidities. The study design reported that participants would receive baseline examinations and be tested monthly in laboratory. Magnetic resonance imagining (MRI) exams were repeated every second month, and quality of life questionnaires were completed every third month. The researchers allowed any number of prior treatments or recurrences of disease without limits. More than 85% of trial participants had failed two or more prior lines of chemotherapy (i.e., = second recurrence), and nearly 20% had failed (or had a recurrence) while being treated with bevacizumab prior to enrollment. Tumor response and progression were determined by a blinded central radiology review. This study was designed to demonstrate device superiority over the pharmaceutical control.

The trial's primary outcome was overall survival (OS). Secondary endpoints were: progression-free survival (PFS), the percentage of individuals alive and progression-free at 6 months (PFS6), 1-year survival rate, radiological response rate (RR), quality of life, and safety. OS and PFS were computed from randomization until event or censored at last follow-up utilizing Kaplan–Meier survival method, with 2-sided log rank statistics for comparison. The study had an 80 percent power at a significance level of 0.05 to detect a 60 percent increase in median OS (Hazard Ratio [HR] 0.63). All analyses were performed using the intent to treat population of all randomized participants, individuals lost to follow-up were censored at the time of last contact. Treatment compliance limitations were disproportionately observed in the study as only 78% (93/120) completed one full cycle of the TTFields. Nearly a quarter of all participants in the TTFields treatment arm were noncompliant and discontinued, or failed to begin treatment. 113 of 117 participants (97%) in the active control group started chemotherapy, and all but one person completed one full treatment course. The study presented with follow-up limitations. Twenty-one participants randomized to the control group failed to return to the treatment site, limiting information on disease progression and toxicity. Moreover, quality of life, a secondary

outcome of the study, was only available for assessment on 63 or 27% of trial participants.

Compliance was recorded for those individuals in the TTFields arm who began treatment (n=116) by device downloads. The downloads recorded the treatment duration that TTFields **therapy** was delivered to each participant. The observed median compliance rate was 86 percent (41–98%) during each treatment month, resulting into a mean duration use of 20.6 hours per day. The study acknowledged variance among the level of disease progression (i.e., first recurrence versus multiple) by the participants but failed to produce comparisons amongst the control groups. Missing these comparisons limits the study's ability to determine the overall effectiveness of the TTFields as a monotherapy. Participants received either single agent or a combination of chemotherapeutic regimens. The percentage breakdown for the chemotherapy agents prescribed were as follows: individuals received bevacizumab (31%), or irinotecan (31%), followed by nitrosoureas (25%), carboplatin (13%), temozolomide (11%) or various other agents (5%). However, the study reported that among individuals treated with the active chemotherapy control, survival was not significantly affected by the choice of chemotherapeutic agent ( $p = 0.66$ ).

The statistical analysis of the survival data was tested for proportional hazards and the assumption of proportionality met using the Cox proportional hazards regression model. The Cox model was performed in two steps; first, all protocol pre-specified baseline variables were tested directly for interactions with OS; then a reduced model was performed testing the effect of all variables with significant interaction ( $p < 0.05$ ) with OS together on the treatment effect of TTFields versus active chemotherapy. At a median follow-up of 39 months, 220 trial participants had succumbed to their disease (93%). The primary endpoint failed to demonstrate a significant increase in mean overall survival between the two treatments. Median survival failed to report statistical significance but was marginally higher in the TTFields group compared to active control chemotherapy (6.6 versus 6.0 months, respectively). One-year survival proportion was 20% in both groups and was unable to demonstrate superiority over common chemotherapy treatments. The 2- and 3-year survival rates were reported as 8% (95% CI, 4-13) and 4% (95% CI, 1-8) versus 5% (95% CI, 3-10) and 1% (95% CI, 0-3) for TTFields versus active control, respectively. The reported hazard ratio was 0.86 (95% CI, 0.66-1.12) in favor of TTFields ( $p = 0.27$ ), indicating that TTFields may be at least equivalent and trending toward an improvement as compared to active chemotherapy. The trial failed to report statistically significant device superiority. Participants were not restricted based on prior treatments or recurrences. Many of the participants presented with advanced disease at trial initiation. As many as 40% of participants were included after the third disease occurrence, possibly decreasing the potential benefit from treatment. Trial results showed TTFields as a monotherapy provided similar, not superior, efficacy as best physician's choice chemotherapy in individuals afflicted with recurrent GBM, albeit superior quality of life and less toxicity resulting from treatment with chemotherapy.

Secondary trial outcomes were presented without adjustment. Quality of life measures were assessed using the QLQ-C30 questionnaire with brain-specific module (BN-20), and the measurements were presented as the change from baseline to 3 months for each of the subscale domains and symptoms scale. The researchers reported that both cognitive and emotional functioning were higher in the TTFields group compared to the chemotherapy group, with no difference in global health. The researchers reported that more objective radiological responses (partial and complete responses) were seen in the TTFields group than in the active control chemotherapy group (14 versus 7, respectively). Progression-free survival (PFS) resulted marginally in favor of participants in the TTFields treatment group, with median PFS reported as 2.2 and 2.1 months for TTFields versus the active control group, respectively (HR 0.81, 95% CI 0.60 - 1.09; log rank  $p = 0.16$ ). Authors state progression-free survival at 6 month was 21.4 percent (95% CI 13.5 - 29.3) in the TTFields group and 15.1 percent (95% CI 7.8 - 22.3) in the active control group (chi squared  $p = 0.13$ ). The authors were unable to claim statistical significance for the trial outcomes.

This study was limited by the inability to be blinded, which could introduce bias and compromise the quality of life assessments. Participant knowledge of their active participation limits the pinnacle prognostic factor by creating bias. The disproportionate dropout rates are concerning. Many individuals stopped treatment prior to completing one month of treatment duration, and these individuals failed to be treated long enough to make substantial contributions to assist with determinations on device effectiveness. High rates of participant cross-over from chemotherapy into device treatment were observed in the study. Due to the nature of this disease and the dismal prognosis for individuals in this patient population, even marginal changes in overall survival and any increase in quality of life are clinically significant findings, as alternative to the current treatment modalities for individuals with recurrent GBM. Based on the slight improvement, trends observed in this trial suggest that treatment with TTFields may be considered an option.

Kanner et al performed a post hoc analysis to study the intent-to-treat (ITT) population in the TTFields treatment versus the best physician's choice chemotherapy. The authors report overall survival was significantly affected by duration that the TTFields device was worn. Not surprising, since this treatment is without a half-life and would require continuous application of the device to demonstrate a reduction in tumor growth. Stratifying population size to augment the desired results, the post hoc analysis measured outcomes within the population who fully completed at least one cycle (four weeks) of TTFields treatment. Based on those modifications, the researchers observed individuals who complied with treatment protocol of = 18 hours daily (n=92) had significantly longer overall survival medians, 7.7 versus 4.5 months than those who used treatment = 18 hours (n=28). Small sample sizes in the study diminish this power of the analysis, and the device may create adherence bias. However, a therapeutic response resulting in an observed mean overall survival increase of three months supports treatment effectiveness when compliance of the treatment protocol is adhered to.

A Patient Registry Dataset (PRiDe) followed 457 persons with recurrent GBM who received TTFields **therapy** was studied by Mrugala et al in a real-world, phase IV setting. Additional information on the safety and effectiveness of the **therapy** was assessed in the dataset. The primary outcome of the registry evaluated median overall survival, tolerability of the device, participant compliance and survival, and other prognostic factors. Mrugala reported overall survival (OS) and treatment using Kaplan-Meier methods and Cox proportional hazards model assessed participant characteristics and disease prognostic factors on survival. Evaluation was conducted with log-rank tests to compare OS and daily compliance, prior debulking surgery, Karnofsky Performance Score (KPS), number of recurrence, and prior bevacizumab use.

Overall survival between the PRiDe participants and those treated in the the seminal study with TTFields **therapy**, and physician's best chemotherapy, increased from 9.6 versus 6.6 versus 6.0 months, respectively. Overall survival rates at one- and two- years increased when compared to treatment arms (TTFields and chemotherapy) from the EF-11 study and PRiDe. As stated above, evidence supported daily compliance as a prognostic factor in TTFields **therapy**. Participants who achieved the recommended daily compliance of =18 hours a day had significantly longer ( $p=.0001$ ) overall survival --- 13.5 months versus 4.0 months when individuals reported less than =18 hours. Subgroup analysis of individuals treated at first recurrence (n=152) demonstrated the longest median overall survival, resulting in 20 months. The overall survival reported in the first recurrence population is similar to more recent studies on the newly diagnosed, suggesting that TTFields may be an option as an effective **therapy** in GBM recurrence, if treatment is initiated at earliest recurrence.

The registry failed to evaluate participant use of combination **therapy** with TTFields and prescription programs, such as chemotherapy and anti-vascular endothelial growth factor agents. Outside of a clinical trial, the lack of recording information on other medical management regimens for participants resulted in critically missed analyses in demonstrating the effectiveness of TTFields as a **therapy**, potentially misrepresenting the true effectiveness of the device in the largest studied population. The registry highlights compliance as a key finding, supporting the adaptation of TTFields; however, it failed to record compliance data for more than one-third of all device users. Device safety and tolerability was proven outside of observational settings. Consistent with other trials, the adverse event most commonly observed was

associated with device-related skin irritation.

The registry presented with limitations, including lack of quality of life measures, as these were excluded in the real world follow-up, an important prognostic factor in overall health outcome from the original trial. Heterogeneity limitations exist within the registry as 67% of the total population were male (n=309), possibly significant considering the need to shave a user's scalp for successful placement of the treatment arrays when utilizing this device.

**TUMOR TREATING FIELDS FOR THE TREATMENT OF NEWLY DIAGNOSED GLIOBLASTOMA MULTIFORME**

Stupp et al. 2015 conducted a multi-center, open-label, randomized phase III trial designed to evaluate the efficacy and safety of TTFields following chemoradiation with temozolomide (TMZ) for treatment of newly diagnosed glioblastoma. The trial enrolled 695 participants with histologically confirmed supra-tentorial glioblastoma, who were progression-free following debulking surgery or biopsy, and who have completed standard concomitant chemoradiotherapy with TMZ. These individuals were randomized (2:1) to receive combination **therapy** of TTFields plus temozolomide (TMZ) (n=466) or standard maintenance chemotherapy alone using TMZ (n=229). Randomization was stratified by participant characteristics: degree of resection, and O6-methylguanine-DNA methyltransferase (MGMT) methylation status. The primary outcome was progression-free survival (PFS) in the intent-to-treat (ITT) population and was assessed by independent reviewers (80% power; hazard ratio [HR], 0.78; allowing for 10% loss to follow-up; 2-sided a level of 0.05). This study investigated shifted overall survival to a secondary outcome but with equal power (HR, 0.76; 2-sided a = 0.05). To avoid an increase in the risk of a false positive result, overall survival was to only be tested statistically if the PFS was achieved.

In October, 2014, a safety monitoring committee reviewed the findings of an interim analysis reporting on the first 315 participants enrolled in the TTFields plus temozolomide (n=210) and temozolomide (n=105) treatment groups. Pre-specified endpoints were achieved in the intent-to-treat population. After a median follow-up of 38 months (18-60 months), the median PFS in the TTFields plus TMZ arm was 7.1 months from randomization (95% confidence interval [CI], 5.9 - 8.2 months) compared to 4.0 months (95 % CI, 3.3 - 5.2) in the control group ([HR] 0.62; 98.7% CI, 0.43 - 0.89; stratified log-rank, P= 0.001). Overall survival in the per-protocol analysis also showed significant improvement. The combination **therapy** group (n=196) resulted in median OS of 20.5 months (95% CI, 16.7 - 25.0 months) compared to 15.6 months (95% CI, 13.3 - 19.1 months) in the TMZ alone group (n=84) ([HR], 0.64; 99.4% CI, 0.42 - 0.98; P =0.004). Based on the results of the interim analysis, the trial was terminated, and participants in the control group were allowed to receive TTFields. The termination resulted in eleven individuals in the interim analysis and twenty-six participants overall to cross over and receive TTFields treatment. The study demonstrated the addition of TTFields to temozolomide treatment increased median progression-free survival in the ITT population by 3.1 months.

Per the study design, if tumor progression occurred, second-line chemotherapy was offered by local investigator's practice. Noteworthy, TTFields would continue in the treatment arm, until the second radiological confirmed progression, or clinical deterioration, for a maximum of 24 months. Brain imaging was routinely performed, initially at baseline with contrast-enhanced magnetic resonance imaging (MRI) at two weeks prior to treatment initiation, then in two-month intervals until second radiologically confirmed progression in all study participants. Two-thirds of the TTFields plus TMZ group (n=141) continued treatment with TTFields beyond first tumor progression. The trial design to stop at second tumor progression may have clinical importance when considering the progression of disease and the use of TTFields as a treatment option for individuals transitioning from a new diagnosis into recurrent GBM.

The authors reported median treatment duration of 5.8 months (1 - 58 months) with TTFields. Three-quarters (n=157) of enrollees receiving TTFields adhered to **therapy**. Protocol adherence was considered wearing the device = 18 hours per day on average during the first 3 treatment months. Further analyses in the ITT population showed the median overall survival was 19.6 months (95% CI, 16.6 - 24.4 months) in the TTFields plus temozolomide group compared to 16.6 months (95% CI, 13.6 - 19.2 months) in the temozolomide alone group ([HR],0.74 95% CI, 0.56 - 0.98; stratified log-rank P=0.03). The percentage of those affected by GBM alive at 2 years following enrollment was 43% in the TTFields plus temozolomide group and 29% in the TMZ alone group (P=0.006, a 14% increase of participants alive at two years in the treatment arm.

The original publication (interim analysis) of the EF-14 study was limited by the investigators stopping the trial earlier and allowing participant cross over. The interim analysis was completed after the initial 315 enrollees reached 18 month follow-up. The results in the initial per-protocol population only evaluated 196, 84 participants in the combination **therapy** (TTFields plus TMZ) or the TMZ alone arms, respectively. Additionally, as an open-label trial, no sham or placebo treatment was available for the control group. Investigators deemed the use of sham to be unethical, and impractical, and therefore the potential power of a placebo cannot be assessed. This may introduce adherence bias. The researchers acknowledge placebo bias would be unlikely to influence overall survival and progression-free survival. Following the original trial, which reported results that failed to provide evidence of statistically significant improvements in median overall survival, the primary study outcome shifted between the two seminal trials. In the original EF-11 trial, the primary endpoint was overall survival, and in this trial researchers adjusted the primary outcome to progression-free survival. The results of this study on newly diagnosed GBM, the addition of TTFields to maintenance temozolomide chemotherapy significantly prolonged progression-free and improved overall survival.

Stupp et al 2017 reported on the final analysis inclusive of the entire trial population (n=695) from the open- label, randomized phase III trial designed to evaluate the effect of TTFields plus temozolomide (TMZ) versus maintenance TMZ alone on survival for individuals with glioblastoma. Stupp et al previously published the results from an interim analysis on the first 395 participants of the same study. The primary outcomes were consistent to the interim analysis.

The data set was locked on December 28, 2016, and the authors reported median treatment duration of 8.2 months (1 - 82 months) with TTFields. After a medium follow-up of 40 months (34 - 66 months), the median progression-free survival was 6.7 months (95% CI, 6.1 - 8.1 months) for individuals treated with combination **therapy** versus 4.0 months (95% CI, 3.8 - 4.4 months) for those treated with TMZ alone ([HR] 0.63, 95% CI, 0.52 - 0.76; P <0.001). The secondary outcome reported median overall survival duration of 20.9 months from randomization (95% CI, 19.3 - 22.7 months) in the TTFields plus TMZ group versus 16.0 months (95% CI, 14.0 - 18.4 months) for TMZ only ([HR],0.63; 95% CI, 0.53 - 0.76; P<0.001). Both were found to be statistically and clinically significant. Analyzing the percentage of living participants over selected time periods from randomization resulted in 46% alive at 2 years, 26% alive at 3 years, and 13% alive at 5 years in the combination **therapy** arm, compared to the TMZ only arm reporting 31% alive at 2 years (p <0.001); 16% at 3 years (P=0.009); and 5% at 5 years (P =0.004). Significant percentage increases across each selected time period favoring adjuvant TTField **therapy**.

The median time to randomization was equal among the treatment arms with 3.8 month (range 1.7 - 6.2) and 3.7 months (range, 1.4 - 6.3) in the combination **therapy**, and the TMZ alone treatment groups, respectively. Kaplan-Meier estimates for survival were accessed at 6 months for the rate of progression-free survival between the two treatment groups. The authors reported on progression-free survival at 6 months as 56% (95% CI, 51% - 61%) for the TTFields group and 37% (30% - 44%) with TMZ only (P < 0.001). Cox proportional hazards analyzed both overall survival and progression-free survival across factors: trial arms, age, sex, MGMT status, location, and county of residence. Results using Cox proportional hazards with 95% confidence intervals demonstrated several prognostic factors significantly improved OS; these

prognostic factors include: TTFields treatment group (HR, 0.63, 0.53 - 0.76, P<0.001), female sex (HR, 0.76, 0.63 - 0.92, P = .005), MGMT status (HR, 0.50, 0.41 - 0.62; P < 0.001), younger age (measured continuously, [HR], 0.978 per year, 0.969 - 0.985; P < 0.001), and higher KPS (as a categorical variable in 10 point increments P <0.001).

Interestingly, fifty-five percent of participants had a gross tumor resection (95% of tumor removed) and 13% had only a biopsy performed, results indicating the extent of excision was not statistically significant when investigating overall survival (P= 0.183). The addition of TTFields was not associated with an increase in systemic adverse events (AE) (48% versus 44%; P=0.58). Higher rates of AE found in the TTFields treated group were attributed to longer duration of TMZ treatment in the experimental group as a result of delayed disease progression. Investigators report inclusive criteria for TTFields treatment utilizing Karnofsky Performance Score (KPS). KPS is a scale measuring the ability of individuals to perform ordinary tasks. KPS scores range from 0 to 100; a higher score means a person is better able to carry out daily activities. The author reported time to sustain 10 point reduction in KPS significantly longer for the combination group versus the group treated with only TMZ (5.5 months; 95% CI, 5.0 - 6.3 months versus 3.9 months; 95% CI, 3.1 - 5.2 months, respectively; [HR], 0.80; 95% CI, 0.67 - 0.95; P =0.009).

Potentially important for future studies, a small majority of the experimental population (51%; n=237) continued TTFields treatment beyond first treatment progression. The investigators may want to evaluate, in the newly diagnosed population who elect to continue TTFields as a combination **therapy** beyond first progression, whether significant improvements are observed in progression-free survival and OS compared to the outcomes of the historical recurrent population. The recurrent population only has the option to utilize TTFields as a monotherapy. The largest study to date utilizing the TTFields technology presented with similar limitations as observed in the interim analysis (no sham, burden of use when utilizing the device). Another limitation in the final analysis was that quality of life data points were not recorded. Also, participant heterogeneity limitations exist since nearly 70% of the study participants were male and 89% were white.

The final analysis for the treatment of glioblastoma utilizing the TTFields technology demonstrated that the combination **therapy** of TTFields and temozolomide chemotherapy following standard concomitant TMZ and radiotherapy has shown to significantly improve progression-free survival and overall survival in the newly diagnosed population.

NovoCure Inc. of Portsmouth, New Hampshire (subsidiary of NovoCure Ltd., Haifa, Israel) was granted approval for the NovoTTF-100A system. The NovoTTF-100A Treatment Kit received US Food and Drug Administration (FDA) Premarket Approval on April 8, 2011 (P100034). The current supplement Optune™ System, which received FDA Premarket Approval on October 5, 2015 (P1000034/S013) was submitted to expand the indications for use: Optune™ System with temozolomide is indicated for the treatment of adult patients with newly diagnosed, supra-tentorial glioblastoma following maximal debulking surgery and completion of radiation **therapy** together with concomitant standard of care chemotherapy.

In summary, TTFields has been demonstrated to be a safe and effective alternative treatment, and should be considered for individuals with either recurrent or newly diagnosed Glioblastoma. In 2015, The National Comprehensive Cancer Network® (NCCN®) clinical practice guidelines appropriateness in the treatment of central nervous system cancer for use of TTFields has shifted to consider category 3 in the recurrent population as a category 2B. A 2B category allows providers to consider the use of TTFields in treatment of recurrent disease. The NCCN® 2016 guidelines classifies alternating electronic **fields therapy** as a 2A grade for newly diagnosed glioblastoma individuals. NCCN® guidelines demonstrate TTFields used in concomitant treatment with adjuvant temozolomide following radiotherapy and concomitant temozolomide for the newly diagnosed. Indicating that use of TTFields could be used an initial treatment **therapy**, when prescribed with adjuvant temozolomide.

**TUMOR TREATING FIELDS IN OTHER INDICATIONS**

Researchers have initiated evaluations utilizing NovoCure's TTFields technology in the treatment of other solid tumor indications. The various populations actively being investigated include cancers such as: non-small cell lung (NSCLC), brain metastases (1-5; 1-10) from NSCLC, pancreatic, ovarian, mesothelioma, and high grade glioma and ependymoma in children. Each of these separate indications has been either recently completed or is actively being studied in phase II trials to determine safety and efficacy with this new modality. The trials range in size, n= 5 in the child study to 82 participants in the mesothelioma trial. Variance exists between the primary outcomes researched in each of the new indications. In the ovarian and pancreatic cancers, the primarily investigated outcome was device related adverse effects and feasibility based on compliance as a result of the individual's early discontinuation of treatment. The tumor location could be a factor in compliance. Toxicity was the principal measurement in the non-small cell lung cancer study, whereas overall survival was the primary outcome in the mesothelioma trial. All studies listed time to progression, or progression-free survival as a secondary endpoint.

Non-small cell lung cancer is currently under investigation, with participants actively enrolled into a prospective, randomized controlled phase III trial aimed to test the efficacy and safety of TTFields in combination with PD-1 inhibitors or docetaxel as a second-line treatment. The researchers will assess the overall survival of participants with the TTFields and docetaxel or PD-1 inhibitors versus docetaxel or PD-1 alone in a superiority study design. Interestingly, if the primary outcome fails, the researchers will evaluate overall survival of those treated with TTFields and docetaxel versus PD-1 inhibitors alone in a separate, more challenging non-inferiority study. This study has a completion date of December 2020.

Evaluation of a trial on the feasibility of Optune for children with recurrent or progressive supra-tentorial high-grade glioma and ependymoma cancers was initiated in early 2017. This trial aims to demonstrate use of the Optune device as a feasible treatment option in the pediatric population and report treatment-related toxicities assessed by Common Terminology Criteria for Adverse Events v4.0. A total of 25 children are expected to participate in this trial. This study was the first trial, inclusive of the pivotal trials, that utilizes the TTFields technology that was not funded or sponsored by the device manufacture, NovoCure, Ltd. The pediatric study is sponsored by Pediatric Brain Tumor Consortium, with support from the National Cancer Institute (NCI).

Coding

Inclusion of a code in this table does not imply reimbursement. Eligibility, benefits, limitations, exclusions, precertification/referral requirements, provider contracts, and Company policies apply.

The codes listed below are updated on a regular basis, in accordance with nationally accepted coding guidelines. Therefore, this policy applies to any and all future applicable coding changes, revisions, or updates.

In order to ensure optimal reimbursement, all health care services, devices, and pharmaceuticals should be reported using the billing codes and modifiers that most accurately represent the services rendered, unless otherwise directed by the Company.

The Coding Table lists any CPT, ICD-9, ICD-10, and HCPCS billing codes related only to the specific policy in which they appear.

CPT Procedure Code Number(s)

N/A

Professional and outpatient claims with a date of service on or before September 30, 2015, must be billed using ICD-9 codes.  
Professional and outpatient claims with a date of service on or after October 1, 2015, must be billed using ICD-10 codes.

Facility/Institutional inpatient claims with a date of discharge on or before September 30, 2015, must be billed with ICD-9 codes.  
Facility/Institutional inpatient claims with a date of discharge on or after October 1, 2015, must be billed with ICD-10 codes.

ICD - 10 Procedure Code Number(s)

N/A

Professional and outpatient claims with a date of service on or before September 30, 2015, must be billed using ICD-9 codes.  
Professional and outpatient claims with a date of service on or after October 1, 2015, must be billed using ICD-10 codes.

Facility/Institutional inpatient claims with a date of discharge on or before September 30, 2015, must be billed with ICD-9 codes.  
Facility/Institutional inpatient claims with a date of discharge on or after October 1, 2015, must be billed with ICD-10 codes.

ICD -10 Diagnosis Code Number(s)

- C71.0 Malignant neoplasm of cerebrum, except lobes and ventricles
- C71.1 Malignant neoplasm of frontal lobe
- C71.2 Malignant neoplasm of temporal lobe
- C71.3 Malignant neoplasm of parietal lobe
- C71.4 Malignant neoplasm of occipital lobe
- C71.5 Malignant neoplasm of cerebral ventricle
- C71.8 Malignant neoplasm of overlapping sites of brain

HCPCS Level II Code Number(s)

- A4555 Electrode/transducer for use with electrical stimulation device used for cancer treatment, replacement only
- E0766 Electrical stimulation device used for cancer treatment, includes all accessories, any type

## Clinical UM Guideline

**Subject:** Electric Tumor Treatment Field (TTF)  
**Guideline #:** CG-DME-44  
**Status:** New

**Publish Date:** 06/28/2018  
**Last Review Date:** 05/03/2018

### Description

This document addresses electrical fields known as “tumor treatment fields (TTF)” that are created by low-intensity, intermediate frequency (100–200 kilohertz [kHz]) electric currents delivered to the malignant tumor site by insulated electrodes placed on the skin surface. TTF are felt to cause tumor cell death (apoptosis) by disrupting the assembly of microtubules during later stages of cell division.

### Clinical Indications

#### Medically Necessary:

The use of FDA approved devices to generate electric tumor treatment fields (TTF) to treat histologically-confirmed supratentorial glioblastoma (known also as glioblastoma multiforme [GBM] or World Health Organization [WHO] grade IV astrocytoma) is considered **medically necessary as adjunctive treatment** when **all** of the following criteria below are met:

- Initial treatment with debulking surgery or biopsy followed by chemoradiation with concomitant temozolomide and radiotherapy has been completed with no documented tumor progression\*; **and**
- TTF is used in combination with temozolomide; **and**
- TTF is initiated within 7 weeks from final dose of temozolomide and radiotherapy; **and**
- Individual has Karnofsky Performance Status score of 70 or higher **or** Eastern Cooperative Oncology Group (ECOG) performance status 0-1; **and**
- Individual or caregiver has been trained and is willing and able to apply and maintain the device at least 18 hours every day.

\*Progression is defined as tumor growth greater than 25% compared to smallest measured tumor area **or** the appearance of one or more new GBM lesions in the brain.

#### Not Medically Necessary:

The use of devices to generate electric tumor treatment fields (TTF) is considered **not medically necessary** when the criteria above are not met and for all other malignant tumors.

### Coding

*The following codes for treatments and procedures applicable to this guideline are included below for informational purposes. Inclusion or exclusion of a procedure, diagnosis or device code(s) does not constitute or imply member coverage or provider reimbursement policy. Please refer to the member's contract benefits in effect at the time of service to determine coverage or non-coverage of these services as it applies to an individual member.*

#### CPT

77299 Unlisted procedure, therapeutic radiology clinical treatment planning [when specified as plan for using an electrical stimulation device for TTF]

#### HCPCS

A4555 Electrode/transducer for use with electrical stimulation device used for cancer treatment, replacement only  
 E0766 Electrical stimulation device used for cancer treatment, includes all accessories, any type

#### ICD-10 Diagnosis

C71.0-C71.9 Malignant neoplasm of brain  
 Z85.841 Personal history of malignant neoplasm of brain

### Discussion/General Information

According to the NCI (2018), glioblastoma (WHO grade IV astrocytoma) is also known as GBM. The peak incidence for GBM occurs between the ages of 45 and 70 years. Glioblastoma is highly invasive and is the most frequently occurring brain tumor accounting for approximately 12% to 15% of all brain tumors and 50% to 60% of all astrocytic tumors. Giant cell glioblastoma and gliosarcoma are two histologic variants of glioblastoma multiforme. According to the NCCN (2018) GBM is the “deadliest brain tumor with only a third of patients surviving for one year and less than 5% living beyond 5 years.”

The Optune (formerly NovoTTF-100A System) was approved by the FDA in April 2011, as a novel device to treat adults age 22 years or older with GBM that recurs or progresses after receiving chemotherapy and radiation therapy. TTF technology is also

being studied as a treatment for other solid tumors such as non-small cell lung cancer and melanoma. There are published data from TTF use to treat tumors in pre-clinical trials and from small case series. However, the published evidence does not support that long term safety and efficacy of TTF has been established when used as a treatment of tumors other than GBM. On October 5, 2015 the FDA granted approval for use of Optune in combination with temozolomide to treat adults age 22 years or older with newly diagnosed, supratentorial GBM after maximal debulking surgery and completion of radiation therapy together with concomitant standard of care chemotherapy.

The use of electric fields and the corresponding effects upon living tissue has been studied in the laboratory and clinical settings. At very low frequencies alternating electric fields (below 1 kHz) cause membrane depolarization which stimulates excitable tissue (Kirson 2004, 2007, 2009; Salzberg, 2008). Electric fields in the tens of kHz to megahertz (intermediate frequency) alternate too fast to stimulate tissue and results in minute heating. Kirson and colleagues (2004) demonstrated targeted inhibitory effects on dividing cells with the application of alternating electric fields of very low intensity (less than 2 V/centimeter [cm]) and intermediate frequency, called TTF. Utilizing time-lapse microphotography of mouse melanoma cell cultures, unique cellular processes as a result of TTF exposure were identified. Prolongation of mitosis in TTF-treated cells was statistically significant, and one-quarter of the treated cells were destroyed. Cellular destruction was observed only in mitotic cells, and cells at rest (quiescent) remained intact, both functionally and morphologically. Nuclear rotation was also observed in TTF-treated cell cultures. Microtubules, in the form of spatially organized mitotic spindles in dividing cells, have very large electric dipole moments that may be disoriented by TTF forces. In the control cell cultures, 95% of the mitotic spindles were intact and exhibited normal features in cells undergoing mitosis compared to 50% of abnormal cell activity in TTF-treated cultures. The use of TTF was then applied in vivo, to two animal tumor models (adenocarcinoma and malignant melanoma cells). TTF-treated tumors were significantly smaller compared to the control tumor size, and the surrounding normal tissue was spared from injury. The encouraging preclinical data led to studies of electric TTF treatment in humans based on the principle that TTF results in disruption of the cell membrane and programmed cell death of cancer cells.

### ***Glioblastoma Multiforme (GBM)***

The current standard of treatment for newly diagnosed GBM consists of tumor resection followed by daily low-dose temozolomide administered concurrently with external beam radiotherapy followed by adjuvant temozolomide with alternating electric field therapy (NCCN, 2018). Radiochemotherapy is followed by adjuvant temozolomide given for 6 to 12 months. The prognosis for individuals with GBM is poor, with a 1-year survival rate of less than 40%.

The U.S. Food and Drug Administration (FDA) approved the premarket approval application (PMA) for NovoTTF<sup>TM</sup>-100A System (NovoCure<sup>TM</sup> Ltd., Portsmouth, NH; Haifa, Israel) in 2011. The device is now marketed as Optune<sup>TM</sup> (NovoCure Ltd., Portsmouth, NH, Haifa, Israel). Optune is a portable, non-invasive device that is designed for the delivery of TTF to the head. The device is considered to be an alternative to standard medical therapy for GBM after surgical and radiation treatment options are exhausted. Initially, Optune (NovoTTF) was approved as a solitary treatment for adults (22 years of age or older) with histologically-confirmed, recurrent GBM in the supratentorial region of the brain after receiving chemotherapy. On October 5, 2015, the FDA approved the use of Optune in combination with temozolomide for the treatment of adults with newly diagnosed, supratentorial glioblastoma following maximal debulking surgery and radiation therapy.

Stupp and colleagues (2015) evaluated the safety and efficacy of TTF in individuals with newly diagnosed GBM following chemoradiation therapy. In a multi-center clinical trial, 695 individuals were randomized (2:1) to either TTF with temozolomide or temozolomide alone. The primary endpoint was identified as progression-free survival (PFS) in the intent-to-treat (ITT) population (significant threshold,  $p \leq 0.01$ ). An interim analysis was designed into the study to be conducted on the first 315 participants who had completed at least 18 months of follow-up. At interim analysis, the median PFS in the TTF plus temozolomide group was 7.1 months (95% confidence interval [CI], 5.9-8.2 months) compared to 4.0 months (95% CI, 3.3-5.2 months) in the temozolomide group (Hazard Ratio [HR] 0.62; 98.7% CI, 0.43-0.89; stratified log-rank,  $p=0.001$ ). The secondary endpoint, the overall survival (OS) in the per-protocol population also showed significant improvement in the treatment group versus control. Median overall survival in the per-protocol population in the TTF plus temozolomide group versus the temozolomide alone group was 20.5 months (95% CI, 16.7-25.0 months) and 15.6 months (95% CI, 13.3-19.1 months) respectively (HR, 0.64; 99.4% CI, 0.42-0.98;  $p=0.004$ ). Based on the interim analysis results, the study was terminated and individuals in the control group were offered TTF in addition to temozolomide. A total of 11 individuals crossed over and began using TTF. With the exception of a higher incidence of localized skin reactions in the TTF plus temozolomide group, the incidence, distribution, and severity of adverse events were similar across both treatment groups. This trial does contain a few limitations. As enrollment was not initiated until following radiochemotherapy, this initial phase of treatment is subject to variability. Participants were excluded from participation for progression during early radiotherapy; therefore, those with a very poor prognosis were not included in the sample population. In addition, as TTF was continued beyond tumor progression, there was additional data on this group, increasing the potential for reporting bias. The final analysis of the data was consistent with the interim analysis results (Stupp, 2017).

Stupp and associates (2012) conducted a phase III, multinational, randomized controlled pivotal clinical trial upon which the initial PMA was based. Between September 2006 and May 2009, 28 clinical centers enrolled 237 adult participants with relapsed or progressive GBM despite conventional therapy (e.g., surgery and chemo-radiotherapy followed by chemotherapy). A total of 120 participants were randomized in a 1:1 ratio to receive monotherapy with NovoTTF treatment and 117 participants were randomized to the group treated with available best standard care (BSC) chemotherapies as practiced at each of the participating clinical centers. Chemotherapy agents considered as BSC during the trial included platinum-based chemotherapy (i.e., carboplatin); nitrosureas (BCNU); procarbazine; combination of procarbazine, lomustine and vincristine (PCV); temozolomide; and bevacizumab. A period of 28 days of treatment with NovoTTF was considered 1 full treatment course. Participants treated with NovoTTF were allowed to take breaks from treatment up to an hour, twice per day for personal needs such as showers. The primary endpoint of the study was OS. Secondary endpoints included PFS at 6 months (PFS<sub>6</sub>), time-to-progression (TTP), 1-year survival rate, quality of life (QOL), and radiological response. Participants were seen in clinic monthly, and magnetic resonance imaging (MRI) was performed after 2, 4, and 6 months from initiation of treatment and subsequent

MRIs were done according to local practice until disease progression. Medical follow-up continued for 2 months after disease progression. Monthly telephone interviews with the participants' caregivers were used to assess participant mortality rates.

Of the 237 enrollees, 8 participants (4 in each group) did not receive the assigned therapy. A total of 97% (116) of 120 enrollees in the NovoTTF group started treatment and 93 participants (78%) completed 1 cycle (4 weeks) of therapy. Discontinuation of TTF occurred in 27 participants due to noncompliance or the inability to handle the device. For each TTF treatment month, the median compliance was 86% (range 41-98%), which equaled a mean use of 20.6 hours per day. In the BSC (active control) group, 113 (97%) of the 117 assigned participants received chemotherapy and all completed 1 full treatment course with the exception of 1 individual. In the BSC cohort, 21 participants did not return to the site and details on disease progression and toxicity were not available. Stupp and colleagues (2012) noted the median survival of 6.6 months in the TTF group was marginally higher than 6 months in the BSC group (HR 0.86, 95% CI, 0.66–1.12;  $p=0.27$ ). For both groups, 1-year survival was 20%. The survival rates for 2 and 3 years were 8% (95% CI: 4, 13) and 4% (95% CI: 1, 8) versus 5% (95% CI: 3, 10) and 1% (95% CI: 0, 3) for the TTF cohort compared to the BSC cohort, respectively. With a median follow-up of 39 months, 93% (220 participants) had died. Objective radiological responses (partial response [PR] and complete response [CR]) were noted in 14 participants in the TTF group and 7 in the BSC group, with a calculated response rate of 14.0% (95% CI, 7.9-22.4%) compared to 9.6% (95% CI, 3.9-18.8%), respectively. Sixteen percent of the TTF participants had grade 1 and 2 contact dermatitis on the scalp, which resolved with topical steroids. BSC participants experienced grade 2-4 events by organ system related to the pharmacologic activity of chemotherapy agents utilized. QOL data were available in 63 participants (27%). Based on the Quality of Life Questionnaire-Core 30 (QLQ C-30) and Brain Cancer Module (BN-20) questionnaires, 5 out of 6 general scales and 7 of 9 symptom scales including nausea, vomiting, diarrhea, constipation and pain, QOL was consistently higher in NovoTTF than in the control group. There were no meaningful differences observed between the domains of global health and social functioning. The BSC cohort had a larger decrease in the negative effects of seizures than the TTF cohort. The self-reporting of QOL indicators may be influenced by bias for the treatment group (FDA Label, 2011; Stupp, 2012). Although the NovoTTF-100A device has received FDA approval, the pivotal trial did not achieve the primary endpoint of the study, which was improved survival with NovoTTF treatment in comparison to chemotherapy.

In an industry-sponsored study, Kirson and colleagues (2007) reported results of TTF treatment on various tumor cell lines and animal tumor models and noted "Optimal frequencies differed between cancer cell types." Additionally, the effects of a total of 280 weeks of TTF treatment on 10 individuals with recurrent GBM were reported in the pilot study. TTF treatment resulted in a median TTP of 26.1 weeks (range, 3-124 weeks) and the PFS6 of 50% (23-77% CI). The median OS was 62.2 weeks (range, 20.3-124.0 weeks). One individual achieved a CR and is free from tumor 10 months after stopping treatment, and 1 participant achieved and continues to maintain a PR 7 months after stopping treatment. The authors concluded TTF treatment is encouraging when compared to historical average PFS6 of  $15.3 \pm 3.8\%$  and average historical TTP of  $9.5 \pm 1.6$  weeks and an average OS  $29.3 \pm 6$  weeks. Mild to moderate contact dermatitis was reported in 9 out of 10 participants.

Results from an industry-sponsored pilot study of TTF alone and TTF in combination with chemotherapy for individuals with diagnosed GBM were reported (Kirson, 2009b). In this single arm study, the first group included 10 individuals with recurrent GBM after failure of maintenance temozolomide, and 10 individuals with newly diagnosed GBM treated with TTF combined with temozolomide were in the second cohort. All 20 individuals were treated for an average of 1 year (range 2.5-24 months) continuously. The first group was compared to a matched group of 18 concurrent controls who received salvage chemotherapy for relapsed/recurrent GBM. The TTF-chemotherapy group was compared to a matched group of 32 concurrent controls who received temozolomide alone. In addition, OS for both cohorts was compared to matched historical control data. Data for the first group were reported by Kirson and colleagues in 2007. For the group of 10 individuals with newly diagnosed GBM, PFS was significantly different (HR 3.32; 95% CI, 1.9-5.9;  $p=0.0002$ ) between the TTF-chemotherapy group compared to the matched concurrent and historical controls. The difference in OS was also significant ( $p=0.0018$ ). The authors concluded TTF may also be an effective sensitizer when used concurrently with chemotherapeutic agents.

Vymazal and colleagues (2015) analyzed the response patterns in individuals who exhibited an objective response in two previous studies in order to evaluate the baseline characteristics of those individuals who responded and to evaluate the relationship between compliance with use and efficacy outcomes. The analysis was completed on one pilot study ( $n=10$ ) and a phase III trial ( $n=237$ ) in which TTF was compared to standard chemotherapy. Between both studies, TTF was administered as monotherapy in 130 individuals. Across both trials, there was a 15% response rate (16/110 with a 4% CR rate). There were no significant differences in baseline characteristics between the responder and nonresponder groups. In those in which a response was noted, there was frequently a delayed response; the tumor would initially continue to grow before responding to treatment. Analysis supported that an increase in compliance was associated with better treatment response and longer OS. The extent of treatment response in those who exhibited a response was dependent on compliance ( $p<0.001$ ).

Treatment recommendations for brain tumors published by the National Comprehensive Cancer Network® (NCCN, 2018) and the National Cancer Institute (NCI, 2017) include surgical resection, radiation therapy and/or chemotherapy as treatment options. In 2014, the NCCN clinical practice guideline for CNS Tumors was updated and the consideration for alternating electric field therapy for individuals with recurrent, diffuse or multiple GBM was changed to a category 3 from the previous 2B level of evidence, denoting major disagreement on the appropriateness of the intervention. In May 2015, the NCCN clinical practice guideline was again revised to change the recommendation to consider alternating electric field therapy for glioblastoma from a category 3 back to a category 2B for recurrent disease. In 2018, NCCN added a category 1 recommendation for adjuvant alternating electric field therapy when used as an initial therapy along with temozolomide for individuals with anaplastic gliomas/glioblastoma with good performance status following standard radiotherapy and concurrent temozolomide. The NCI Adult Brain Tumors Treatment (PDQ®) (2018) does not include TTF treatment for recurrent GBM.

#### **Other Solid Tumors**

In addition to TTF treatment for brain tumors, this therapy has been studied in other types of malignancies, including breast cancer, non-small cell lung cancer (NSCLC) and pancreatic carcinoma. However, at this time, there are no studies which

support that the use of tumor treating fields for conditions other than GBM. The NCCN clinical practice guidelines do not include any recommendations regarding the use of electric TTF treatment for any condition other than GBM.

## Definitions

**Cytokinesis:** The cytoplasmic changes accompanying mitosis. The cleavage of the cytoplasm into daughter cells following nuclear division.

**Eastern Cooperative Oncology Group (ECOG) Performance Status:** A scale used to determine the individual's level of functioning. This scale may also be referred to as the WHO or Zubrod score which is based on the following scale:

- |   |   |
|---|---|
| 0 | Fully active, able to carry on all pre-disease performance without restriction  |
| 1 | Restricted in physically strenuous activity but ambulatory and able to carry out work of a light or sedentary nature, e.g., light house work, office work |
| 2 | Ambulatory and capable of all self-care but unable to carry out any work activities. Up and about more than 50% of waking hours                           |
| 3 | Capable of only limited self-care, confined to bed or chair more than 50% of waking hours   |
| 4 | Completely disabled. Cannot carry on any self-care. Totally confined to bed or chair  |
| 5 | Dead  |

**Glioblastoma multiforme:** Stage IV glioblastoma, which includes WHO recognized variants, giant cell glioblastoma and gliosarcoma.

**Karnofsky Performance Status Score:** A 10 point scale used by healthcare providers to quickly evaluate how an individual is feeling on any given day.

- |     |   |
|-----|---|
| 100 | Able to work. Normal; No complaints; No evidence of disease.                        |
| 90  | Able to work. Able to carry on normal activity; Minor symptoms.                     |
| 80  | Able to work. Normal activity with effort; Some symptoms.                           |
| 70  | Independent; not able to work. Cares for self; Unable to carry on normal activity.  |
| 60  | Disabled; dependent. Requires occasional assistance; cares for most needs.          |
| 50  | Moderately disabled; dependent. Requires considerable assistance and frequent care. |
| 40  | Severely disabled; dependent. Requires special care and assistance.                 |
| 30  | Severely disabled. Hospitalized, death not imminent.                                |
| 20  | Very sick. Active supportive treatment needed.                                      |
| 10  | Moribund. Fatal processes are rapidly progressing                                   |

**Mitosis:** The process by which a single parent cell divides to make two new daughter cells. Each daughter cell receives a complete set of chromosomes from the parent cell, allowing the body to grow and replace cells.

**Progressive disease:** Disease that is growing, spreading or getting worse.

**Recurrent disease:** Disease that has recurred (come back), usually after a period of time during which the disease could not be detected. In the case of cancer, the disease may come back to the same place as the original (primary) tumor or to another place in the body: also called recurrence.

## ***Tumor Treating Fields Therapy for Glioblastoma***

**Effective:** May 1, 2018

**Next Review:** February 201

**Last Review:** March 2018

### **IMPORTANT REMINDER**

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

### **DESCRIPTION**

Glioblastoma multiforme is the most common and deadly form of malignant brain tumor in adults. It has a very poor prognosis and is associated with low quality of life during the course of treatment. Tumor treating fields therapy is a new, noninvasive technology that is intended to treat glioblastoma using electrical fields.

### **MEDICAL POLICY CRITERIA**

- I. Tumor treating fields (TTF) to treat primary supratentorial glioblastoma multiforme (GBM) may be considered **medically necessary** when all of the following are met:
  - A. Patient is 18 years of age or older; and
  - B. Documentation of histologically-confirmed primary supratentorial GBM; and
  - C. Following radiation and chemotherapy; and
  - D. Concurrent treatment with temozolomide (TMZ), unless TMZ has been ineffective, not tolerated, or is contraindicated.
- II. The use of mapping software to optimize TTF therapy may be considered **medically necessary** for GBM when patients meet criterion I. above.
- III. The use of TTF and/or TTF-associated mapping software is considered

**investigational** when the above criterion I. is not met.

*NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.*

## POLICY GUIDELINES

It is critical that the list of information below is submitted for review to determine if the policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

- History and Physical/Chart Notes
- Documentation of histologically-confirmed primary supratentorial glioblastoma multiforme (GBM)
- Radiation and chemotherapy history
- Documentation of Temozolomide (TMZ) maintenance treatment and response

## CROSS REFERENCES

## BACKGROUND

Glioblastoma multiforme (GBM) are the most common and deadly malignant brain tumor. Glioblastoma is the most common malignant primary brain tumor in adults, with a median age at diagnosis of 64 years.<sup>[1]</sup> GBMs are grade IV astrocytomas, the most deadly type of glial cell tumor, and are often resistant to standard chemotherapy. According to the National Comprehensive Cancer Network (NCCN), GBM is the "deadliest brain tumor with only a third of patients surviving for 1 year and less than 5% living beyond 5 years."<sup>[2]</sup>

The primary treatment for GBM is debulking surgery to remove as much of the tumor as possible. At that time, some patients may undergo implantation of the tumor cavity with a carmustine bis chloroethylnitrosourea (BCNU)-impregnated wafer.<sup>[2]</sup> Depending on the patient's physical condition, adjuvant radiation therapy, chemotherapy (typically temozolomide [TMZ]), or a combination of the two are sometimes given. After adjuvant therapy, some patients may undergo maintenance therapy with TMZ. In patients with disease that recurs after these initial therapies, additional debulking surgery may be used if recurrence is localized. Treatment options for recurrent disease include various forms of systemic medications such as bevacizumab, bevacizumab plus chemotherapy (e.g., irinotecan, BCNU/chloroethylnitrosourea (CCNU), TMZ), TMZ, nitrosourea, PCV (procarbazine, CCNU, and vincristine), cyclophosphamide, and platinum-based agents.<sup>[2]</sup> Response rates in recurrent disease are less than 10%, and progression-free survival rates at 6 months are less than 20%.<sup>[2,3]</sup>

## TUMOR TREATING FIELDS THERAPY

Tumor Treating fields (TTF) therapy is a new, noninvasive technology that is intended to treat GBM on an outpatient basis using electrical fields.<sup>[3-5]</sup> TTF therapy exposes cancer cells to alternating electric fields of low intensity and intermediate frequency, which are purported to both selectively inhibit tumor growth and reduce tumor angiogenesis. TTF are proposed to inhibit rapidly dividing tumor cells by 2 mechanisms, arrest of cell proliferation and destruction of cells while undergoing division.<sup>[4,5]</sup>

The Optune™, formerly known as NovoTTF-100A™ System, (Novocure Inc.) has been approved by the U.S. Food and Drug Administration (FDA) to deliver TTF therapy. TTF therapy via the Optune™ is delivered by a battery-powered, portable device that generates the fields via disposable electrodes that are noninvasively attached to the patient's shaved scalp over the site of the tumor.<sup>[3,4]</sup> The device is used by the patient at home on a continuous basis (20-24 hours per day) for the duration of treatment, which can last for several months. Patients can carry the device in a backpack or shoulder pack while carrying out activities of daily living.<sup>[3,4]</sup>

## **NOVOTAL™ SYSTEM**

The NovoTAL™ (Transducer Array Layout) System (Novocure Inc.) is a proprietary software tool that produces a custom transducer array layout to optimize Optune therapy for each patient. The software accomplishes this by maximizing the intensity of Tumor Treating Fields (TTFields) based on MRI measurements of the head, tumor size and location(s) and optimizing TTFields distribution.

## **REGULATORY STATUS**

Optune™, (assigned the generic name of TTF) was approved by Food & Drug Administration (FDA) in April 2011 through the premarket approval (PMA) process.<sup>[6]</sup> FDA-approved indication for use are:

“Optune™ is intended as a treatment for adult patients (22 years of age or older) with histologically-confirmed glioblastoma multiforme (GBM).

Optune™ with temozolomide (TMZ), is indicated for the treatment of adult patients with newly diagnosed, supratentorial glioblastoma following maximal debulking surgery and completion of radiation therapy together with concomitant standard of care chemotherapy. (FDA PMA approval granted in October 2015)

For the treatment of recurrent GBM, Optune™ is indicated following histologically- or radiologically-confirmed recurrence in the supratentorial region of the brain after receiving chemotherapy. The device is intended to be used as a monotherapy, and is intended as an alternative to standard medical therapy for GBM after surgical and radiation options have been exhausted.”<sup>[7]</sup>

The NovoTAL™ System, was approved by the FDA in November 2013 through a PMA supplement for the Optune™ System. It is the software approved for use by physicians certified to prescribe the Optune™ System.

## **EVIDENCE SUMMARY**

### **PRIMARY GLIOBLASTOMA MULTIFORME**

In 2015, Stupp published interim results of a randomized controlled trial (RCT) regarding the safety and efficacy of TTF used in combination with temozolomide maintenance treatment after chemoradiation therapy for patients with GBM.<sup>[8]</sup> Patients were randomized in a 2:1 fashion to receive maintenance treatment with TTF and TMZ (n=466) or TMZ only (n=229). Study eligibility required patients to be 18 years or older, have a histologically confirmed supratentorial glioblastoma, be progression-free after having undergone maximal safe debulking surgery when feasible or biopsy, and have completed standard concomitant

chemoradiotherapy with TMZ. The median time from diagnosis to randomization was 3.8 months in both groups and patients were not blinded due to ethical concerns. TTF was delivered continuously (> 18 hours/day) via 4 transducers placed on the shaved scalp and TMZ (150-200 mg/m<sup>2</sup>/d) was given for 5 days of each 28-day cycle. Transducer array layouts were determined using the NvoTAL mapping software system for TTF fields to optimize field intensity within the treated tumor. A planned interim analysis was to be conducted on the first 315 patients at 18 months follow-up. The primary study endpoint was progression-free survival (PFS) in the intent-to-treat populations (with a significance threshold of .01) with overall survival (OS) in the per-protocol population (n = 280) as a powered secondary endpoint (significance threshold of .006). A total of 695 patients were enrolled across 83 centers; however the trial was terminated as it met its efficacy endpoints at interim analysis (median 38 months, 315 patients).

The interim analysis included the planned 315 subjects, with 210 in the TTF/TMZ group and 105 in the TMZ only group. The analysis was conducted at a median 38 months follow-up (range, 18-60 months). Prespecified per-protocol median PFS in the TTF/TMZ group was 7.1 months (95% CI, 5.9-8.2 months) compared to 4 months (95% CI, 3.3-5.2 months) in the TMZ only group (hazard ratio [HR], 0.62 [98.7% CI, 0.43-0.89]; P = .001). The median OS in the per-protocol population was statistically improved in the TTF/TMZ group (20.5 months; 95% CI, 16.7-25.0 months) compared to the TMZ only group (15.6 months; 95% CI, 13.3-19.1 months; HR, 0.64 [99.4% CI, 0.42-0.98]; P = .004). An additional analysis of the intention-to-treat population demonstrated and OS of 19.6 months (95% CI, 16.6-24.4 months) in the TTF/TMZ group compared to 16.6 months (95% CI, 13.6-19.2 months) in the TMZ only group (HR, 0.74 [95% CI, 0.56-0.98]; stratified log-rank p = .03). Forty-three percent of patients in the TTF/TMZ group were alive at 2-year follow-up, compared to 29% in the TMZ only group (p = .006).

These interim results demonstrate an approximate three-month improvement of PFS and five-month improvement of OS when TTF therapy is used concurrently with TMZ in patients with newly diagnosed GBM.

In 2017, Stupp published final results from this trial, including all 695 subjects.<sup>[9]</sup> From the time of randomization, median progression-free survival was 6.7 months in the TTF/TMZ group, and 4.0 months in the TMZ only group (HR, 0.63; 95% CI, 0.52-0.76; P < .001). Median overall survival was 20.9 months in the TTF/TMZ group as compared to 16.0 months in the TMZ only group (HR, 0.63; 95% CI, 0.53-0.76; P < .001). The application of TTF therapy in addition to TMZ treatment compared to TMZ treatment alone was not associated with an increase in adverse events (48% vs 44%, P = 0.58). Mild to moderate skin irritation was observed in 52% of patients who received TTF/TMZ treatment.

## **RECURRENT GLIOBLASTOMA MULTIFORME**

The literature on the efficacy of TTF therapy in patients with recurrent GBM consists of small, single-arm studies and two RCTs.

### **Randomized Controlled Trials**

The use of TTF and the corresponding effects on living tissue have been studied in clinical settings.<sup>[10-12]</sup> For example, in 2007, Kirson, reported the findings of a case study examining the effects of TTF therapy delivered by the NovoTTF-100A System in 10 patients with recurrent GBM.<sup>[10]</sup> Median time to progression (TTP) in these patients was 26.1 weeks and

median overall survival (OS) was 62.2 weeks. The authors noted that these TTP and OS values were more than double the reported medians of historical control patients. No device-related serious adverse events were seen after more than 70 months of cumulative treatment in all of the patients. The only device-related adverse event observed was a mild-to-moderate contact dermatitis beneath the field delivering electrodes. The primary limitation of this study was the use of historical controls, since the patients included may not be comparable on major clinical and prognostic features.<sup>[10]</sup>

These preliminary findings served as a basis for a 2012 prospective Phase III multinational RCT by Stupp, which was sponsored and funded by the manufacturer of the device (NovoCure). This study compared TTF therapy (delivered by the NovoTTF-100A System) to the best standard of care chemotherapy (active control).<sup>[3]</sup> Twenty-eight clinical centers (across 7 countries) enrolled 237 adult participants with relapsed or progressive GBM, despite conventional radiotherapy. Other prior treatments may have included surgery and/or chemotherapy. Patient characteristics were balanced in both groups, with median age of 54 years and median Karnofsky performance status (KPS) of 80%. More than 80% of participants had failed 2 or more prior chemotherapy regimens ( $\geq$  second recurrence), and 20% had failed bevacizumab prior to study enrollment.<sup>[3]</sup>

Two hundred thirty-seven patients were randomized in a 1:1 ratio to receive TTF therapy only (n=120) or active control (n=117). The choice of chemotherapy regimens varied, reflecting local practice at each of the participating clinical centers.<sup>[3]</sup> Chemotherapy agents considered as active control during the trial included platinum-based chemotherapy (i.e., carboplatin); nitrosureas; procarbazine; combination of procarbazine, lomustine and vincristine (PCV); temozolomide; and bevacizumab. For patients assigned to the TTF group, uninterrupted treatment was recommended, although patients were allowed to take treatment breaks of up to 1 hour, twice per day, for personal needs (e.g., shower). In addition, patients assigned to the TTF group were allowed to take 2 to 3 days off treatment at the end of each of 4-week period (which is the minimal required treatment duration for TTF therapy to reverse tumor growth). A period of 28 days of treatment with TTF was considered 1 full treatment course.<sup>[3]</sup>

The primary study end point in this RCT was OS.<sup>[3]</sup> Secondary end points included progression-free survival (PFS) at 6 months, total time to progression (TTP), 1-year survival rate, quality of life (QOL), and radiological response. Participants were seen in clinic monthly, and magnetic resonance imaging (MRI) was performed after 2, 4, and 6 months from initiation of treatment, with subsequent MRIs done according to local practice until disease progression. Medical follow-up continued for 2 months after disease progression. Monthly telephone interviews with the participants' caregivers were used to assess participant mortality rates.<sup>[3]</sup>

Ninety-seven percent (116) of 120 participants in the TTF group started treatment and 93 participants (78%) completed 1 cycle (4 weeks) of therapy. Discontinuation of TTF therapy occurred in 27 participants (22%) due to noncompliance or the inability to handle the device.<sup>[3]</sup> For each TTF treatment month, the median compliance was 86% (range, 41%-98%), which equaled a mean use of 20.6 hours per day. In the active control group, 113 (97%) of the 117 assigned participants received chemotherapy and all except 1 individual completed a full treatment course. Twenty-one participants (18%) in the active control group did not return to the treating site and details on disease progression and toxicity were not available.<sup>[3]</sup>

This RCT did not reach its primary end point of improved survival compared to active

chemotherapy.<sup>[3]</sup> With a median follow-up of 39 months, 220 participants (93%) had died. Median survival was 6.6 months in the TTF group compared to 6.0 months in the active control group (hazard ratio, 0.86; 95% confidence interval [CI], 0.66 to 1.12;  $p=0.27$ ). For both groups, 1-year survival was 20%. The survival rates for 2- and 3-year survival were 8% and 4%, respectively, for the TTF group versus 5% and 1%, respectively, for the active control group. PFS rate at 6 months was 21.4% in the TTF group, compared to 15.1% in the active control group ( $p=0.13$ ). Objective radiological responses (partial and complete response) were noted in 14 participants in the TTF group and 7 in the active control group, with a calculated response rate of 14.0% (95% CI, 7.9% to 22.4%) compared to 9.6% (95% CI, 3.9% to 18.8%), respectively. Sixteen percent of the TTF participants had grade 1 and 2 contact dermatitis on the scalp, which resolved with topical corticosteroids. Active control participants experienced grade 2-4 events by organ system related to the pharmacologic activity of chemotherapy agents utilized; severe (grades 3 and 4) toxicity was observed in 3% of participants.<sup>[3]</sup>

Longitudinal QOL data were available in 63 participants (27%).<sup>[3]</sup> There were no meaningful differences observed between the groups in the domains of global health and social functioning. However, cognitive, emotional, and role functioning favored TTF therapy, whereas physical functioning favored chemotherapy. Symptom scale analysis was in accordance to treatment-associated toxicity; appetite loss, diarrhea, constipation, nausea, and vomiting were directly related to the chemotherapy administration. Increased pain and fatigue was reported in the chemotherapy-treated patients and not in the TTF group.

In summary, this RCT failed to demonstrate the primary end point of improved survival with TTF therapy in comparison to chemotherapy.<sup>[3,13]</sup> Limitations of the trial included a somewhat heterogeneous patient population, with participants included after progression of 1 or several lines of chemotherapy, as well as the use of different chemotherapy regimens in the control group. Another limitation is the absence of a placebo/supportive care arm. In the setting of advanced disease, the supportive care arm would have been useful to gauge the safety and efficacy of treatment for both groups of patients. Treatments used in the active control arm (best standard of care chemotherapy) in the recurrent disease setting have previously demonstrated limited efficacy, thus limiting the ability to determine the true treatment effect of TTF. Data from a trial of TTF versus placebo, or of TTF plus standard chemotherapy versus standard chemotherapy alone would therefore provide a better assessment of treatment efficacy.

A further limitation was high dropout rates in both groups. For example, over 20% of participants in the active control group were lost at follow-up, and this may have underestimated the toxicity evaluation in this group. Similarly, over 20% of participants in the TTF arm discontinued treatment within a few days due to noncompliance or inability to handle the device. This implies that compliance might be an issue with TTF, as it requires the patient to continuously wear transducers on the shaved head. Finally, the number of patients who completed the QOL data was approximately one-quarter of total enrollment, and the self-reported QOL indicators may have been subject to bias due to the lack of blinding.<sup>[3,6]</sup> Therefore, due to the numerous methodologic limitations, evidence from this trial is not sufficient to demonstrate that TTF therapy results in improved health outcomes for patients with recurrent GBM.

Post hoc subgroup analyses of these trial data have been published in abstract form comparing outcomes of patients between both groups who had failed bevacizumab prior to

study enrollment.<sup>[14,15]</sup> For example, Wong et al., published a subgroup analysis of the previously described RCT to determine characteristics of responders and nonresponders in the treatment and active control groups.<sup>[16]</sup> Tumor response was assessed by the Macdonald criteria. More patients in the TTF arm were considered responders (14/120 vs 7/117 in the chemotherapy arm.) Median response time was longer for those in the TTF arm than the chemotherapy arm (7.3 months vs 5.6 months,  $p < 0.001$ ), and there was a strong correlation (Pearson's  $r$ ) between response and OS in the TTF arm ( $p < 0.001$ ) but not in chemotherapy arm ( $p = 0.29$ ). Compared with the chemotherapy arm, a higher proportion of responders in the TTF arm had a prior low-grade histology (36% vs 0%). These differences in treatment responder groups suggest that TTF therapy may differentially benefit certain types of GBM; however, the small numbers of responders in both groups limits generalizations that can be drawn from this analysis.

## **Nonrandomized Studies**

A study published in late 2014 included OS data from 457 patients included in the Patient Registry Dataset (PRiDe), a postmarketing registry of all recurrent GBM patients who received NovoTTF therapy in a real-world, clinical practice setting in 91 centers.<sup>[17]</sup> The median OS rate in the PRiDe clinical practice dataset was reported as significantly superior to that attained in the TTF pivotal trial (9.6 months vs 6.6 months; HR=0.66, 95% CI, 0.05 to 0.86;  $p < 0.001$ ). One- and 2-year OS rates for TTF in PRiDe were significantly longer than those in the TTF group in the pivotal RCT (44% vs 20% at 1 year; 30% vs 9% at 2 years, respectively). The PRiDe investigators reported no novel or unexpected treatment-related adverse events compared with the pivotal RCT. These results, although promising, are limited by a lack of randomized comparison group with which to isolate the direct effect of TTF therapy upon symptom improvement and overall outcomes.

In addition, two very small case series have also been published of long-term survival (>6 years) with TTF therapy.<sup>[18,19]</sup> Since the approval of the NovoTTF device, additional case reports and very small case series ( $n=3-5$ ) have been reported.<sup>[20-22]</sup>

## **NOVOTAL™ SYSTEM**

### **Nonrandomized Studies**

In 2016, Connelly published a small feasibility study using the NovoTAL™ System with nonstandard non-contrast enhancement and advanced imaging.<sup>[23]</sup> All patients presented with gliomas (grades 2-4) and had previously received standard therapy prior to initiation of TTFields. A standard pre- and postcontrast MRI scan was acquired and used for TTFields treatment planning, in conjunction with other imaging modalities. Eight patients were reported on in this series: three underwent T2 imaging, one underwent FLAIR, one used diffusion weighted imaging, and one used MR-perfusion imaging. This case series demonstrates that treatment planning beyond the extent of contrast enhanced MRI is clinically feasible but it must be prospectively compared to standard treatment planning in a clinical trial setting, in order to determine the impact on patient outcomes.

In 2015, Chaudhry et al. evaluated physician performance in conducting transducer array layout mapping using the NovoTAL™ System compared with mapping performed by the Novocure in-house clinical team.<sup>[24]</sup> Fourteen physicians (seven neuro-oncologists, four medical oncologists, and three neurosurgeons) evaluated five blinded cases of recurrent glioblastoma. Concordance for each physician versus Novocure on 20 MRI measurements

was 0.96 (standard deviation, SD  $\pm$  0.03, range 0.90-1.00), indicating very high agreement between the two groups, indicating that physicians prescribing TTFields, when trained on the NovoTAL™ System, can independently perform transducer array layout mapping required for the initiation and maintenance of patients on TTFields therapy. This study did not address clinical utility.

## PRACTICE GUIDELINE SUMMARY

### NATIONAL COMPREHENSIVE CANCER NETWORK

The National Comprehensive Cancer Network (NCCN) clinical practice guidelines on Central Nervous Systems Tumors (v.1.2017) recommend TTF therapy in conjunction with standard brain radiation therapy and current/adjuvant temozolomide for patients with supratentorial disease with good performance status. This is a category 3 recommendation. The panel conceded that data regarding TTF therapy is limited to evidence from the Stupp RCT which demonstrated similar survival in between groups. In addition, in the background section, the panel indicated that TTF therapy may be considered as a treatment option for recurrent GBM but not all panelists recommend treatment for these patients due to a lack of efficacy. The NCCN guideline does not address the use of TTF therapy recommendation section for patients with recurrent disease.<sup>[2]</sup>

## SUMMARY

The research on the safety and efficacy of tumor treating fields (TTF) therapy for patients with primary glioblastoma has some limitations. However, the small number of studies published do show that TTF therapy improves progression-free and overall survival in adult patients with primary glioblastoma multiforme (GBM) who are receiving concurrent temozolomide (TMZ) treatment. Therefore, TTF therapy may be considered medically necessary when criteria are met. TTF therapy in patients with recurrent glioblastoma multiforme (GBM) is limited to one randomized controlled trial which failed to demonstrate an improvement in overall survival or disease response. Due to insufficient research, the use of TTF therapy is considered investigational when criteria are not met, including but not limited to patients with recurrent glioblastoma.

There is limited research to show that the use of software to optimize tumor treating fields (TTF) therapy (e.g., the NovoTAL™ System) when used in conjunction with TTF therapy improves the outcomes of patients with glioblastoma compared to patients treated with TTF therapy alone. Despite these limitations, the use software to optimize TTF therapy in patients with glioblastoma may be medically necessary when criteria are met. Due to insufficient research, the use of TTF-associated mapping software is considered investigational when criteria are not met.

## CODES

**NOTE:** There is no specific code for the NovoTAL System software program. While some may submit using CPT code 77261, the appropriate CPT code for this service is unlisted code 77299.

Codes	Number	Description
CPT	77261	Therapeutic radiology treatment planning; simple
	77299	Unlisted procedure, therapeutic radiology clinical treatment planning
HCPCS	A4555	Electrode/transducer for use with electrical stimulation device, used for cancer treatment, replacement only
	E0766	Electrical stimulation device, used for cancer treatment, includes all accessories, any type

**Date of Origin:** January 2014

**Name of Policy:****Tumor-Treatment Fields Therapy for Glioblastoma**

Policy #: 536  
Category: DME

Latest Review Date: April 2018  
Policy Grade: C

---

**Background/Definitions:**

*As a general rule, benefits are payable under Blue Cross and Blue Shield of Alabama health plans only in cases of medical necessity and only if services or supplies are not investigational, provided the customer group contracts have such coverage.*

*The following Association Technology Evaluation Criteria must be met for a service/supply to be considered for coverage:*

- 1. The technology must have final approval from the appropriate government regulatory bodies;*
- 2. The scientific evidence must permit conclusions concerning the effect of the technology on health outcomes;*
- 3. The technology must improve the net health outcome;*
- 4. The technology must be as beneficial as any established alternatives;*
- 5. The improvement must be attainable outside the investigational setting.*

*Medical Necessity means that health care services (e.g., procedures, treatments, supplies, devices, equipment, facilities or drugs) that a physician, exercising prudent clinical judgment, would provide to a patient for the purpose of preventing, evaluating, diagnosing or treating an illness, injury or disease or its symptoms, and that are:*

- 1. In accordance with generally accepted standards of medical practice; and*
- 2. Clinically appropriate in terms of type, frequency, extent, site and duration and considered effective for the patient's illness, injury or disease; and*
- 3. Not primarily for the convenience of the patient, physician or other health care provider; and*
- 4. Not more costly than an alternative service or sequence of services at least as likely to produce equivalent therapeutic or diagnostic results as to the diagnosis or treatment of that patient's illness, injury or disease.*

## **Description of Procedure or Service:**

Glioblastoma multiforme is the most common and deadly malignant brain tumor. It has a very poor prognosis and is associated with low quality of life during the course of treatment. Tumor-treating fields' (TTF) therapy is a new, noninvasive technology that is intended to treat glioblastoma using electrical fields.

## **Glioblastoma Multiforme**

Glioblastomas, also known as glioblastoma multiforme (GBM), are the most common form of malignant primary brain tumor in adults, and they comprise approximately 15% of all brain and central nervous system tumors and more than 50% of all tumors that arise from glial cells. The peak incidence for GBM occurs between the ages of 45 and 70 years. GBMs are Grade IV astrocytomas, the most deadly type of glial cell tumor, and are often resistant to standard chemotherapy. According to the National Comprehensive Cancer Network, GBM is the "most lethal brain tumor with only a third of patients surviving for 1 year and less than 5% living beyond 5 years."

## **Treatment**

The primary treatment for patients newly diagnosed with GBM is to safely resect the tumor, and confirm a diagnosis; meanwhile, debulking the tumor to relieve symptoms of increased intracranial pressure or compression. At that time, some patients may undergo implantation with a carmustine (bischloroethylnitrosourea) (BCNU)-impregnated wafer. The cure rate with local treatment is very low; therefore, postsurgical treatment involves the use of adjuvant radiotherapy, chemotherapy (typically temozolomide), or a combination of the 2 therapies. After adjuvant therapy, some patients may undergo maintenance therapy with temozolomide. Prognostic factors for success of therapy are age, histology, and performance status or physical condition of the patient.

No standard treatment exists for recurrent GBM. In patients with disease that recurs after these initial therapies, additional debulking surgery may be used if recurrence is localized. Treatment options for recurrent disease include various forms of systemic medications such as bevacizumab, bevacizumab plus chemotherapy (e.g., irinotecan, BCNU/chloroethylnitrosourea CCNU, temozolomide), temozolomide, nitrosourea, PCV (procarbazine, CCNU, and vincristine), cyclophosphamide, and platinum-based agents.

Fractionated external-beam radiotherapy after surgery is standard adjuvant therapy and also may be used to treat recurrent GBM. Response rates in recurrent disease are less than 10%, and progression-free survival rates at 6 months are less than 20%.

Testing for O6-methylguanine-DNA methyltransferase (MGMT) gene promoter methylation has been proposed as a method to predict which patients with malignant gliomas may benefit from the use of alkylating agent chemotherapy, such as temozolomide. Data from randomized controlled trials have shown that MGMT promoter methylation is a predictor to responding to alkylating chemotherapeutic agents such as temozolomide. The response rate and overall survival with the use of temozolomide are higher in patients who have MGMT promoter methylation. *(See Medical Policy #582 on MGMT promotor methylation in malignant gliomas.)*

### *Tumor Treatment Fields*

Tumor-treating fields (TTF) therapy is a noninvasive technology that is intended to treat GBM on an outpatient basis using electrical fields. TTF therapy exposes cancer cells to alternating electric fields of low intensity and intermediate frequency, which are purported to both selectively inhibit tumor growth and reduce tumor angiogenesis. Tumor-treating fields are proposed to inhibit rapidly dividing tumor cells by 2 mechanisms, arrest of cell proliferation and destruction of cells while undergoing division.

Optune®, formerly NovoTTF-100A System (Novocure, Haifa, Israel) is the only legally marketed TTF delivery system available in the United States. Optune is a portable battery or power supply operated device that produces alternating electrical fields within the human body. These fields are called tumor treatment fields and are applied to the patient's shaved head by means of electrically insulated surface transducer arrays, such that resistively coupled electric currents are not delivered to the patient. The device is used by the patient at home on a continuous basis (20-24 hours a day for the duration of treatment). Patients can carry the device in a backpack or shoulder pack while carrying out activities of daily living.

### *Karnofsky Performance Status (KPS)*

KPS is a standard way of measuring the ability of cancer patients to perform ordinary tasks. KPS scores range from 0 to 100; a higher score means a person is better able to carry out daily activities. For example, a KPS of 60 means a person requires occasional assistance, but is able to care for most of their personal needs. KPS may be used to determine a patient's prognosis, to measure changes in a patient's ability to function, or to decide if a patient could be included in a clinical trial.

### *Supratentorial*

Supratentorial refers to the upper portion of the brain comprised of the cerebrum and the diencephalon.

### *Temozolomide*

Temozolomide is an oral alkylating chemotherapy drug used in the treatment of some brain cancers. It is a first-line treatment for glioblastoma.

The FDA has not approved the use of electric TTF devices for indications other than GBM. Further studies are needed to determine the safety and long-term efficacy of electric TTF therapy for other types of cancer.

## **Policy:**

**Effective for dates of service on or after 04/26/2018:**

**Tumor-treating fields (TTF) therapy meets Blue Cross and Blue Shield of Alabama's medical criteria for coverage to treat histologically-confirmed Supratentorial Glioblastoma (known also as glioblastoma multiforme [GBM], Grade IV) as adjunctive therapy when used according to FDA labeled indications, contraindications, warnings and precautions, and when ALL of the following criteria are met:**

- Initial treatment with debulking surgery or biopsy followed by chemoradiation with concomitant Temozolomide and radiotherapy have been completed; and
- TTF is used in combination with Temozolomide and
- Individual has Karnofsky Performance Status (KPS) score of  $\geq 60$  (requires occasional assistance, but is able to care for most of their personal needs); and
- Individual is age 22 or older and
- Individual or caregiver has been trained and is willing and able to apply the device daily; and
- Individual is willing to wear the device at least 18 hours daily.

**Tumor-treating fields (TTF) therapy meets Blue Cross and Blue Shield of Alabama's medical criteria for coverage to treat recurrence of previously histologically confirmed Supratentorial Glioblastoma (known also as glioblastoma multiforme [GBM], Grade IV) when used according to FDA labeled indications, contraindications, warnings and precautions, and when ALL of the following criteria are met:**

- There is histologically or radiologically confirmed recurrence of supratentorial glioblastoma following treatment with surgery, chemotherapy, and/or radiation and
- TTF is used as monotherapy, and
- Individual has Karnofsky Performance Status (KPS) score of  $\geq 60$  (requires occasional assistance, but is able to care for most of their personal needs); and
- Individual is age 22 or older and
- Individual or caregiver has been trained and is willing and able to apply the device daily; and
- Individual is willing to wear the device at least 18 hours daily.

**Tumor Treatment Fields (TTF) therapy does not meet Blue Cross and Blue Shield of Alabama's medical criteria for coverage when the criteria above are not met and for all other indications.**

**Computer software used for therapeutic radiology clinical treatment planning in conjunction with tumor treatment field (TTF) therapy does not meet Blue Cross and Blue Shield of Alabama's medical criteria for coverage and is considered not medically necessary.**

**Effective for dates of service prior to 04/26/2018:**

**Tumor-treating fields (TTF) therapy for glioblastoma does not meet** Blue Cross and Blue Shield of Alabama's medical criteria for coverage and is considered **investigational** for all indications, including but not limited to the following situations:

- As an alternative to standard chemotherapy for patients with advanced or recurrent glioblastoma multiforme;
- As an adjunct to standard maintenance therapy in patients with glioblastoma multiforme following initial treatment with surgery and/or radiotherapy.

*Blue Cross and Blue Shield of Alabama does not approve or deny procedures, services, testing, or equipment for our members. Our decisions concern coverage only. The decision of whether or not to have a certain test, treatment or procedure is one made between the physician and his/her patient. Blue Cross and Blue Shield of Alabama administers benefits based on the member's contract and corporate medical policies. Physicians should always exercise their best medical judgment in providing the care they feel is most appropriate for their patients. Needed care should not be delayed or refused because of a coverage determination.*

**Key Points:**

The most recent literature review was through June 5, 2017. Following is a summary of the key literature.

Re-radiation options are limited for glioblastoma (GBM) patients who have received initial external-beam radiotherapy due to radiation tolerances. The tumors are locally invasive but do not metastasize, therefore, tumor treating fields (TTF) therapy as a locoregional intervention is proposed a treatment for GBM. Tumor treating fields (TTF) is proposed as a treatment for glioblastoma (GBM). For this review, 2 indications will be considered: (1) TTF as an alternative to chemotherapy in advanced or recurrent GBM and (2) TTF as an adjunct to maintenance treatment in patients following early treatment. Comparative trials are essential to determine efficacy in this area, and randomized controlled trials (RCTs) are needed to control for heterogeneity in the patient populations and other confounders of outcome. This review will include both RCTs and nonrandomized comparative trials.

**TTF as an Alternative to Chemotherapy for Progressive or Recurrent GBM**

**Randomized Controlled Trials**

The U.S. Food and Drug Administration (FDA) approval of the NovoTTF-100A system was based on a Phase III, multinational prospective RCT which was published in 2012 by Stupp et al. The Stupp et al study, which was sponsored and funded by the manufacturer of the device (NovoCure), compared TTF therapy (delivered by the NovoTTF-100A System) to the best standard of care chemotherapy (active control). Twenty-eight clinical centers (across 7 countries) enrolled 237 adult participants with relapsed or progressive GBM, despite conventional radiotherapy. Other prior treatments may have included surgery and/or chemotherapy. Patient characteristics were balanced in both groups, with median age of 54 years and median Karnofsky performance status (KPS) of 80%. More than 80% of participants had failed 2 or more prior chemotherapy regimens ( $\geq$ second recurrence), and 20% had failed bevacizumab prior to study

enrollment. The performance of additional post recurrence debulking surgery was 28% in the TTF arm and 25% in the active treatment arm. Prior low-grade glioma progressing to glioblastoma was present in 8% of each trial arm at baseline.

Two hundred and thirty-seven patients were randomized in a 1:1 ratio to receive TTF therapy only (n=120) or active control (n=117). The choice of chemotherapy regimens varied, reflecting local practice at each of the participating clinical centers. Chemotherapy agents considered as active control during the trial included platinum-based chemotherapy (i.e., carboplatin); nitrosoureas; procarbazine; combination of procarbazine, lomustine and vincristine (PCV); temozolomide; and bevacizumab. For patients assigned to the TTF group, uninterrupted treatment was recommended, although patients were allowed to take treatment breaks of up to 1 hour, twice per day, for personal needs (e.g., shower). In addition, patients assigned to the TTF group were allowed to take 2 to 3 days off treatment at the end of each of 4- week period (which is the minimal required treatment duration for TTF therapy to reverse tumor growth). A period of 28 days of treatment with TTF was considered 1 full treatment course.

This study was designed as a superiority trial. The primary study endpoint in this RCT was overall survival (OS). Secondary endpoints included progression-free survival (PFS) at 6 months, time to progression (TTP), 1-year survival rate, quality of life (QOL), and radiological response. Participants were seen in clinic monthly, and magnetic resonance imaging (MRI) was performed after 2, 4 and 6 months from initiation of treatment, with subsequent MRIs done according to local practice until disease progression. Medical follow-up continued for 2 months after disease progression. Monthly telephone interviews with the participants' caregivers were used to assess participant mortality rates.

One hundred sixteen (97%) of 120 participants in the TTF group started treatment and 93 participants (78%) completed 1 cycle (4 weeks) of therapy. Discontinuation of TTF therapy occurred in 27 participants (22%) due to noncompliance or the inability to handle the device. For each TTF treatment month, the median compliance was 86% (range 41-98%), which equaled a mean use of 20.6 hours per day. In the active control group, 113 (97%) of the 117 assigned participants received chemotherapy and all except 1 individual completed a full treatment course. Twenty-one participants (18%) in the active control group did not return to the treating site and details on disease progression and toxicity were not available.

Outcomes of this study are summarized in Table 1. The trial did not reach its primary endpoint of improved survival compared to active chemotherapy. With a median follow-up of 39 months, 220 participants (93%) had died. Median survival was 6.6 months in the TTF group compared to 6.0 months in the active control group (hazard ratio 0.86; 95% confidence interval [95% CI]: 0.66–1.12; p=0.27). For both groups, 1-year survival was 20%. The survival rates for 2- and 3-year survival were 8% and 4%, respectively, for the TTF group versus 5% and 1%, respectively, for the active control group. Progression-free survival rate at 6 months was 21.4% in the TTF group, compared to 15.1% in the active control group (p=0.13). Objective radiological responses (partial and complete response) were noted in 14 participants in the TTF group and 7 in the active control group, with a calculated response rate of 14.0% (95% CI: 7.9–22.4%) compared to 9.6% (95% CI: 3.9– 18.8%), respectively. Sixteen percent of the TTF participants had Grade 1 and 2 contact dermatitis on the scalp, which resolved with topical steroids. Active control

participants experienced Grade 2 to 4 events by organ system related to the pharmacologic activity of chemotherapy agents utilized; severe (Grades 3 and 4) toxicity was observed in 3% of participants.

Longitudinal QOL data were available in 63 participants (27%). There were no meaningful differences observed between the groups in the domains of global health and social functioning. Cognitive, emotional, and role functioning favored TTF therapy, whereas physical functioning favored chemotherapy. Symptom scale analysis was in accordance to treatment-associated toxicity; appetite loss, diarrhea, constipation, nausea and vomiting were directly related to the chemotherapy administration.

Wong et al (2014) published a subgroup analysis of the previously described RCT to determine characteristics of responders and nonresponders in the treatment and active control groups. Tumor response was assessed by the Macdonald criteria. More patients in the TTF arm were considered responders (14/120 vs 7/117 in the chemotherapy arm.) Median response time was longer for those in the TTF arm than the chemotherapy arm (7.3 months vs 5.6 months,  $p < 0.001$ ), and there was a strong correlation (Pearson's  $r$ ) between response and OS in the TTF arm ( $p < 0.001$ ) but not in the chemotherapy arm ( $p = 0.29$ ). Compared with the chemotherapy arm, a higher proportion of responders in the TTF arm had a prior low-grade histology (36% vs 0%). Dexamethasone use among responders was also significantly lower than that in nonresponders in both NovoTTF-100A and BPC cohorts, responders had a lower daily dexamethasone usage than nonresponders. For the NovoTTF-100A cohort, the respective median and mean daily dexamethasone dose was 1.0 and 2.3 mg (95% CI, 0.8 to 3.8 mg) for responders and 5.2 and 6.8 mg (95% CI, 5.6 to 8.1 mg) for nonresponders ( $p = 0.002$ ). For the BPC chemotherapy cohort, the respective median and mean daily dexamethasone dose was 1.2 and 1.4 mg (95% CI, 0.3 to 2.4 mg) mg for responders and 6.0 and 7.2 mg (95% CI, 6.0 to 8.4 mg) mg for nonresponders ( $p = 0.004$ ). These differences in treatment responder groups suggest that TTF therapy may differentially benefit certain types of GBM; however, the small numbers of responders in both groups limits generalizations that can be drawn from this analysis.

**Table 1: Randomized Trial of TTF Versus Physicians' Choice Chemotherapy in Recurrent Glioblastoma: Principal Efficacy Results from Stupp et al**

Outcomes	TTF	Chemotherapy	Measure of Association, Significance
Median survival, mo	6.6	6.0	
Hazard ratio survival			0.86(95% CI, 0.66 to 1.12) favors TTF
Radiologic response(not all patients evaluated)	14%	9.6%	$p = 0.19$
Median PFS, mo	2.2	2.1	
Hazard ratio PFS			0.81(95%CI, 0.60 to 1.09) favors TTF

CI: confidence interval; PFS: progression-free survival; TTF: tumor treatment fields.

A second post hoc analysis of the TTF EF-11 pivotal trial data was performed to evaluate OS rates among patients who completed at least 1 complete course of TTF or chemotherapy. These investigators analyzed survival in what they referred to as a "modified ITT [intention-to-treat]" subgroup comprising 93 (78%) of 120 of the original TTF allocated group, versus 117 (100%) of

Page 7 of 14

117 of the original chemotherapy allocated group. This exercise revealed median OS of 7.7 months in the TTF modified ITT group compared with 5.9 months in the chemotherapy group (HR=0.69; 95% CI, 0.52 to 0.91; p=0.009). They also showed a trend relationship between proportion of patients with higher TTF compliance and median OS rates (p=0.039). The investigators suggest that TTF provides an OS benefit if used as intended in the FDA-approved label when compared with best chemotherapy. This post hoc analysis is limited as it was not prespecified in the study, includes only 78% of the original TTF allocated patients, and fails to control for noncompliance due to faster clinical deterioration of TTF recipients leading to treatment cessation.

#### Nonrandomized Comparative Studies

Two nonrandomized studies were identified that compared TTF treatment to standard care using historical controls. A study published in late 2014 included OS data from 457 patients included in the Patient Registry Dataset (PRiDe), a postmarketing registry of all recurrent GBM patients who received NovoTTF therapy in a real-world, clinical practice setting in 91 centers in the United States between October 2011 and November 2013. The median OS rate in the PRiDe clinical practice dataset was reported as significantly superior to that attained in the TTF EF-11 pivotal trial (9.6 months vs 6.6 months; HR=0.66, 95% CI, 0.05 to 0.86; p<0.001). One- and 2-year OS rates for TTF in PRiDe were significantly longer than those in the TTF group in the EF-11 trial (44% vs 20% at one year; 30% vs 9% at 2 years, respectively). The PRiDe investigators reported no novel or unexpected treatment-related adverse events compared with the EF-11 trial.

Kirson et al (2007), for example, reported the findings of a case study examining the effects of TTF therapy delivered by the NovoTTF-100A System in 10 patients with recurrent glioblastoma multiforme (GBM). Median time to progression (TTP) in these patients was 26.1 weeks and median overall survival (OS) was 62.2 weeks. The authors noted that these TTP and OS values were more than double the reported medians of historical control patients. No device-related serious adverse events (AEs) were seen after more than 70 months of cumulative treatment in all of the patients. The only device-related AE observed was a mild-to-moderate contact dermatitis beneath the field delivering electrodes. The primary limitation of this study was the use of historical controls, since the patients included may not be comparable on major clinical and prognostic features.

#### Section Summary: Alternative to Chemotherapy in Advanced or Recurrent GBM

The single RCT for this indication reported that outcomes following TTF treatment are similar to outcomes following standard chemotherapy. Overall survival using TTF was noted at 6.6 months versus 6.0 months in the chemotherapy group. There was no placebo control group or supportive care treatment group, and the treatments used in the active control arm (best standard of care chemotherapy) have previously demonstrated limited efficacy. There are several methodologic limitations in the study. There was heterogeneity in the patient populations and heterogeneity in the chemotherapy regimens for the control group. Furthermore, there were more patients in the TTF group than in the control group who did not complete the treatment course, and patients in the TTF group received more courses of second line chemotherapy. People who used TTF in a clinical trial self-reported better quality of life with improved cognitive and emotional functioning compared to people who took chemotherapy. The other available published evidence is 2 nonrandomized comparative studies.

### TTF as an Adjunct to Standard Maintenance Care for GBM

In 2015, Stupp et al published a planned interim analysis of a multicenter, open-label RCT that evaluated maintenance therapy with TTF for GBM. This study enrolled patients with GBM who had completed standard treatment consisting of chemoradiotherapy, plus surgery if indicated. Patients were randomized in a 2:1 fashion to receive either TTF plus temozolomide (vs temozolomide alone). A Karnofsky Performance Score of 70% or higher was an additional inclusion criterion. At the time of the interim analysis, there were 210 patients randomized to TTF plus temozolomide and 105 patients randomized to temozolomide alone. The primary outcome was PFS analyzed by intention-to-treat; a secondary outcome was OS analyzed by per-protocol analysis.

Patients in the TTF group received continuous TTF delivered mainly in the home setting. Patients were trained on use of the device including changing the electrodes, and then treatment continued at home. Patients were encouraged to wear the device continuously, with the exception of short breaks to attend to personal needs. All patients were seen monthly for follow-up. MRI was performed every 2 months and QOL measures administered every 3 months. Tumor progression was adjudicated by a central review committee blinded to treatment group.

Planned interim analysis was performed at a median follow-up of 38 months (range, 18-60 months). Median PFS and median OS are summarized in Table 2.

**Table 2: TTF as an Adjunct to Standard Maintenance Care in GBM**

Group	N	Progression-Free Survival (95% CI)	Hazard Ratio (98.7 CI)	Overall Survival (95% CI)	Hazard Ratio (99.4%CI)
TTF + temozolomide	210(196 <sup>a</sup> )	7.1 mo (5.9 to 8.2 mo)	0.62 (0.43 to 0.89)	20.5 mo (16.7 to 25 mo)	0.64 (0.42 to 0.98)
Temozolomide alone	105(84 <sup>a</sup> )	4.0 mo (3.3 to 5.2 mo)		15.6 (13.3 to 19.1 mo)	

CI: confidence interval; TTF: tumor treatment fields

<sup>a</sup> Included in per-protocol analysis

There were a total of 35 (11%) dropouts during the study, 14 (6.7%) of 210 patients in the TTF group and 21 (20%) of 105 in the temozolomide alone group. Adherence to treatment was defined as wearing the device for at least 18 hours a day, and 157 (75%) of 210 patients met this criteria for adherence. The number of cycles of treatment with temozolomide differed between groups. The TTF group received a median of 6 cycles compared with a median of 4 cycles for the temozolomide alone group. The most common side effect of treatment was local skin irritation, which occurred in 43% of patients treated with TTF.

In October 2014, the trial independent data and safety monitoring committee reviewed the interim analysis, concluding that the trial met its predefined boundaries for success (improvement in PFS and OS) and recommended trial termination. The FDA-approved study termination and the trial was closed to recruitment in November 2014 after 695 of the planned 700 participants had been randomized. All patients in the control maintenance therapy arm were

could crossover to receive TTFs. At the time of the Stupp interim analysis, 35 control arm participants had crossed over.

The FDA considered the results of this analysis for the 2015 expanded approval of Optune®.

#### Section Summary: TTF as an Adjunct to Standard Maintenance Care for GBM

The single RCT for this indication reports that PFS is improved by 3.1 months and OS is improved by 4.9 months after the addition of TTF to standard maintenance therapy. Therefore, there may be a survival benefit associated with TTF for this indication. The single RCT has some methodologic limitations and the current publication is a planned interim analysis. The lack of a placebo group and the lack of blinding create the possibility of a placebo effect, even with the survival outcomes. There was a moderately high rate of dropouts overall (11%) and differential dropout between groups (6.7% in the TTF group vs 20% in standard maintenance group). Also, for the outcomes that were evaluated on a per-protocol basis, such as overall survival, there is the possibility of an adherence bias, in that patients who complete the treatment protocol may have better outcomes than patients who do not complete the protocol.

#### **Summary of Evidence**

For individuals who have advanced or recurrent GBM who receive TTF as an alternative to standard chemotherapy, the evidence consists of one RCT and non-randomized comparative studies. Relevant outcomes include overall survival, progression-free survival, symptoms, functional outcomes, quality of life, and treatment-related morbidity. The single published RCT reported overall survival using TTF at 6.6 months versus 6.0 months in the chemotherapy group. This trial has several methodologic limitations, including the comparisons made include only an active control. There was high dropout, with >20% of patients in each group lost to follow-up, and for the quality of life outcomes only approximately 25% of enrolled patients had complete data. The 2 non-randomized studies were small and have limited validity due to differences in the patient populations treated with TTF and standard care. The evidence is sufficient to determine the effects of the technology on health outcomes.

For individuals who have GBM and who receive TTF as an adjunct to maintenance treatment following initial treatment with surgery and/or radiation, the evidence consists of one RCT. Relevant outcomes include overall survival, progression-free survival, quality of life, and treatment-related morbidity. The single RCT on this question reports that patients who receive TTF treatment plus temozolomide have longer progression-free survival (3.1 months) and overall survival (4.9 months) compared to patients receiving temozolomide alone. The trial has methodologic limitations including the lack of placebo control, differential dropout between groups, and the possibility of adherence bias for outcomes reported with per protocol analysis. The evidence is sufficient to determine the effects of the technology on health outcomes.

#### **Practice Guidelines and Position Statements**

The National Comprehensive Cancer Network guidelines on central nervous system cancers (v.1.2018) include a recommendation for the treatment of glioblastoma. For the initial treatment of patients with glioblastoma with good performance status and either methylated or unmethylated or indeterminate MGMT promotor status, treatment with standard brain radiotherapy plus concurrent temozolomide and adjuvant temozolomide plus alternating electric

currents therapy is a Category 1 recommendation. Alternating electric currents therapy is only an option for patients with supratentorial disease. Consideration of alternating electric field therapy for recurrent glioblastoma is a 2B recommendation...”

#### **U.S. Preventive Services Task Force Recommendations**

Not applicable.

#### **Key Words:**

NovoTTF-100A, NovoTTF, Novocure, TTF, Glioblastoma, GBM, Optune

#### **Approved by Governing Bodies:**

The NovoTTF-100A™ System (Novocure, Haifa, Israel; assigned the generic name of TTF) was approved by the FDA in April 2011 through the premarket approval process. The FDA-approved label reads as follows: “The NovoTTF-100A System is intended as a treatment for adult patients (22 years of age or older) with confirmed GBM, following confirmed recurrence in an upper region of the brain (supratentorial) after receiving chemotherapy. The device is intended to be used as a stand-alone treatment, and is intended as an alternative to standard medical therapy for recurrent GBM after surgical and radiation options have been exhausted.”

On September 28, 2014, FDA approved a request for Novocure to change its products name from NovoTTF-110A System to Optune™.

In October 5, 2015, FDA expanded the indication for Novocure’s use of Optune® in combination with temozolomide to include newly diagnosed GBM. The device was granted priority review status on May 8, 2015 because there was no legally marketed alternative device currently available for the treatment of newly diagnosed GBM that represents a life-threatening condition.

The FDA-approved label reads as follows: “This device is indicated as treatment for adult patients (22 years of age or older) with histologically-confirmed glioblastoma multiforme (GBM). Optune™ with temozolomide is indicated for the treatment of adult patients with newly diagnosed, supratentorial glioblastoma following maximal debulking surgery and completion of radiation therapy together with concomitant standard of care chemotherapy.”

Based on the 2011 approval Optune® is also approved for the treatment of recurrent GBM in the supratentorial region of the brain after receiving chemotherapy. The device is intended for use as a monotherapy, and is intended as an alternative to standard medical therapy for GBM after surgical and radiation options have been exhausted.

#### **Benefit Application:**

Coverage is subject to member’s specific benefits. Group specific policy will supersede this policy when applicable.

ITS: Home Policy provisions apply.

FEP: Special benefit consideration may apply. Refer to member's benefit plan. FEP does not consider investigational if FDA approved and will be reviewed for medical necessity.

### **Current Coding:**

#### **CPT:**

**77299** Unlisted procedure, therapeutic radiology clinical treatment planning

#### **HCPCS Codes:**

**A4555** Electrode/transducer for use with electrical stimulation device used for cancer treatment, replacement only

**E0766** Electrical stimulation device used for cancer treatment, includes all accessories, any type

### **Policy History:**

Medical Policy Panel, August 2013

Medical Policy Group, August 2013 (3): New policy; does not meet medical criteria for coverage and therefore considered investigational

Medical Policy Administration Committee, September 2013

Available for comment September 4 through October 19, 2013

Medical Policy Group, December 2013 (5): 2014 Coding Update- added new codes A4555 and E0766 to current coding effective 01/01/2014

Medical Policy Panel, August 2014

Medical Policy Group, August 2014 (5): Policy updated with literature review through June 26, 2014. Policy Description, Key Points, and References updated. Policy statement unchanged.

Medical Policy Panel, August 2015

Medical Policy Group, August 2015 (6): Updates to Description, Key Points, Approved by Governing Bodies and References; no change to policy statement

Medical Policy Group, May 2016 (6): Added Key Word "Optune"

Medical Policy Panel, August 2016

Medical Policy Group, August 2016 (6): Updates to Policy statement, Key Points, Practice Guidelines and Position Statements, Summary and References. No change in policy intent.

Medical Policy Group, September 2016 (6): Update to Practice Guidelines. No change to policy intent; remains investigational.

Medical Policy Panel, July 2017

Medical Policy Group, July 2017 (6): Updates to Description, Key Points, Practice Guidelines, Governing Bodies and References.

Medical Policy Group, April 2018 (6): Updates to Policy statement to allow coverage of TTF with criteria, Key Points, Practice Guidelines, Coding and References; full literature review to be completed with annual update.

Medical Policy Administration Committee May 2018

Available for comment May 4 through June 17, 2018

Non-Discrimination Statement and Multi-Language Interpreter Services information are located at the end of this document.

Coverage for services, procedures, medical devices and drugs are dependent upon benefit eligibility as outlined in the member's specific benefit plan. This Medical Coverage Guideline must be read in its entirety to determine coverage eligibility, if any.

This Medical Coverage Guideline provides information related to coverage determinations only and does not imply that a service or treatment is clinically appropriate or inappropriate. The provider and the member are responsible for all decisions regarding the appropriateness of care. Providers should provide BCBSAZ complete medical rationale when requesting any exceptions to these guidelines.

The section identified as "Description" defines or describes a service, procedure, medical device or drug and is in no way intended as a statement of medical necessity and/or coverage.

The section identified as "Criteria" defines criteria to determine whether a service, procedure, medical device or drug is considered medically necessary or experimental or investigational.

State or federal mandates, e.g., FEP program, may dictate that any drug, device or biological product approved by the U.S. Food and Drug Administration (FDA) may not be considered experimental or investigational and thus the drug, device or biological product may be assessed only on the basis of medical necessity.

Medical Coverage Guidelines are subject to change as new information becomes available.

For purposes of this Medical Coverage Guideline, the terms "experimental" and "investigational" are considered to be interchangeable.

## **ELECTRIC TUMOR TREATMENT FIELDS (cont.)**

### **Description:**

Electrical field therapy also referred to as Tumor Treatment Field (TTF) therapy exposes cancer cells to alternating electric fields of low intensity and intermediate frequency using insulated electrodes placed on the skin surrounding the region of a malignant tumor to inhibit tumor growth and reduce tumor angiogenesis. TTF inhibit rapidly dividing tumor cells by arrest of cell proliferation and destruction of cells while undergoing division.

FDA-approved TTF devices, include, *but are not limited to*:

- NovoTTF™-100A System
- Optune®

---

### **Criteria:**

- Electric tumor fields for the treatment of histologically-confirmed glioblastoma multiforme (GBM) is considered medically necessary as adjunctive treatment with documentation of **ANY** of the following:
  1. Newly diagnosed glioblastoma in combination with temozolomide following debulking surgery, completion of radiation therapy together with concomitant standard of care chemotherapy
  2. Confirmed recurrence of GBM
- Electric tumor treatment fields for the treatment of other malignant tumors or if criteria above not met is considered **experimental or investigational** based upon:
  1. Insufficient scientific evidence to permit conclusions concerning the effect on health outcomes, and
  2. Insufficient evidence to support improvement of the net health outcome, and
  3. Insufficient evidence to support improvement of the net health outcome as much as, or more than, established alternatives, and
  4. Insufficient evidence to support improvement outside the investigational setting.

## Coverage Policy Manual

**Policy #:** 2013028  
**Category:** DME  
**Initiated:** August 2013  
**Last Review:** July 2018

### Tumor-Treating Fields Therapy

#### Description:

Glioblastoma multiforme is the most common and deadly malignant brain tumor. It has a very poor prognosis and is associated with low quality of life during the course of treatment. Tumor-treating fields therapy is a new, noninvasive technology that is intended to treat glioblastoma using electrical fields.

Glioblastomas, also known as glioblastoma multiforme (GBM), are the most common form of malignant primary brain tumor in adults, and they comprise approximately 15 percent of all brain and central nervous system tumors and over 50 percent of all tumors that arise from glial cells (NCI, 2013). The peak incidence for GBM occurs between the ages of 45 and 70 years. GBMs are grade IV astrocytomas, the most deadly type of glial cell tumor, and are often resistant to standard chemotherapy (NCI, 2013). According to the National Comprehensive Cancer Network (NCCN, 2013), GBM is the "deadliest brain tumor with only a third of patients surviving for one year and less than 5% living beyond 5 years" (NCCN, 2013).

The primary treatment for GBM is debulking surgery to remove as much of the tumor as possible. At that time, some patients may undergo implantation of the tumor cavity with a carmustine (bischloroethylnitrosourea [BCNU]) -impregnated wafer. Depending on the patient's physical condition, adjuvant radiation therapy, chemotherapy (typically temozolomide), or a combination of the two are sometimes given. After adjuvant therapy, some patients may undergo maintenance therapy with temozolomide. In patients with disease that recurs after these initial therapies, additional debulking surgery may be used if recurrence is localized. Treatment options for recurrent disease include various forms of systemic medications such as bevacizumab, bevacizumab plus chemotherapy (eg, irinotecan, BCNU/ chloroethylnitrosourea [CCNU], temozolomide), temozolomide, nitrosourea, PCV (procarbazine, CCNU, and vincristine), cyclophosphamide, and platinum-based agents. Response rates in recurrent disease are less than 10%, and progression-free survival rates at 6 months are less than 20%.

Tumor-treating fields (TTF) therapy is a new, noninvasive technology that is intended to treat GBM on an outpatient basis using electrical fields (Stupp, 2012; Davies, 2013; Pless, 2011). TTF therapy exposes cancer cells to alternating electric fields of low intensity and intermediate frequency, which are purported to both selectively inhibit tumor growth and reduce tumor angiogenesis. Tumor-treating fields are proposed to inhibit rapidly dividing tumor cells by two mechanisms, arrest of cell proliferation and destruction of cells while undergoing division (Davies, 2013; Pless, 2011).

The NovoTTF-100A™ System (Novocure Ltd., Haifa, Israel) has been approved by the Food and Drug Administration (FDA) to deliver TTF therapy. TTF therapy via the NovoTTF-100A™ System is delivered by a battery-powered, portable device that generates the fields via disposable electrodes that are noninvasively attached to the patient's shaved scalp over the site of the tumor (Davies, 2013; Pless, 2011). The device is used by the patient at home on a continuous basis (20–24 hours per day) for the duration of treatment, which can last for several months. Patients can carry the device in a backpack or shoulder pack while carrying out activities of daily living (Davies, 2013; Pless, 2011).

#### Regulatory Status

The NovoTTF-100A™ System (assigned the generic name of TTF) was approved by FDA in April 2011 through the premarket approval process.<sup>6</sup> The FDA-approved label reads as follows: "The NovoTTF-100A System is intended as a treatment for adult patients (22 years of age or older) with confirmed GBM, following confirmed recurrence in an upper region of the brain (supratentorial) after receiving chemotherapy. The device is intended to be used as a stand-alone treatment, and is intended as an alternative to standard medical therapy for recurrent GBM after surgical and radiation options have been exhausted" (US Food and Drug Administration, 2015).

On September 28, 2014, FDA approved a request for Novocure to change its products name from NovoTTF-110A System to Optune™ (Food and Drug Administration, 2014).

On May 11, 2015, FDA granted a priority review status for Novocure's premarket approval supplemental applications for the use of Optune in combination with temozolomide for newly diagnosed glioblastoma (Pharma, 2015).

**Coding**

There are no specific codes for this system or the initial application and instruction on use. The patient reapplies the transducer arrays at home after the initial instruction.

Effective in 2014, there are HCPCS codes for the system and the transducer arrays:

E0766: Electrical stimulation device, used for cancer treatment, includes all accessories, any type

A4555: Electrode/transducer for use with electrical stimulation device, used for cancer treatment, replacement only

**Policy/  
Coverage:**

**Meets Primary Coverage Criteria Or Is Covered For Contracts Without Primary Coverage Criteria**

Tumor treating fields therapy to treat glioblastoma multiforme meets member benefit certificate primary coverage criteria that there be scientific evidence of effectiveness as an adjunct to standard maintenance therapy with temozolomide in patients with newly diagnosed glioblastoma multiforme following initial treatment with surgery, radiotherapy, and/or chemotherapy under the following conditions:

- Adult patients ≥18 years of age
- Karnofsky Performance Status score ≥70%
- Supratentorial tumor.

**Does Not Meet Primary Coverage Criteria Or Is Investigational For Contracts Without Primary Coverage Criteria**

Tumor treating fields therapy does not meet member benefit certificate primary coverage criteria that there be scientific evidence of effectiveness in all other conditions, including but not limited to the following situations:

- As an adjunct to standard medical therapy (eg, bevacizumab, chemotherapy) for patients with progressive or recurrent glioblastoma multiforme
- As an alternative to standard medical therapy for patients with progressive or recurrent glioblastoma multiforme.

For members with contracts without primary coverage criteria, tumor treating fields therapy, including but not limited to the following situations is considered investigational:

- As an adjunct to standard medical therapy (eg, bevacizumab, chemotherapy) for patients with progressive or recurrent glioblastoma multiforme
- As an alternative to standard medical therapy for patients with progressive or recurrent glioblastoma multiforme.

Investigational services are specific contract exclusions in most member benefit certificates of coverage.

**Rationale:**

This policy was created in August 2013 with a search of the MEDLINE database through June 3, 2013. The literature on the efficacy of TTF therapy consists of small, single arm studies and one RCT. Following is a summary of the key literature.

The use of TTF and the corresponding effects upon living tissue have been studied in clinical settings (Kirson, 2007; Kirson, 2009; Salzberg, 2008). Kirson and colleagues (2007), for example, reported the findings of a case study examining the effects of TTF therapy delivered by the NovoTTF-100A System in 10 patients with recurrent GBM (Kirson, 2007). Median time to progression (TTP) in these patients was 26.1 weeks and median overall survival (OS) was 62.2 weeks. The authors noted that these TTP and OS values were more than double the reported medians of historical control patients. No device-related serious adverse events (AEs) were seen after more than 70 months of cumulative treatment in all of the patients. The only device-related AE observed was a

mild-to-moderate contact dermatitis beneath the field delivering electrodes. The primary limitation of this study was the use of historical controls, since the patients included may not be comparable on major clinical and prognostic features (Kirson, 2007).

These preliminary findings served as a basis for a prospective phase III multinational randomized controlled trial (RCT) by Stupp and colleagues (2012), which was sponsored and funded by the manufacturer of the device (NovoCure). This study compared TTF therapy (delivered by the NovoTTF- 100A System) to the best standard of care chemotherapy (BSC, active control) (Stupp, 2012). The FDA approval of the NovoTTF-100A System was based on the results of this RCT. Twenty-eight clinical centers (across seven countries) enrolled 237 adult participants with relapsed or progressive GBM despite conventional radiotherapy. Other prior treatments may have included surgery and/or chemotherapy. Patient characteristics were balanced in both groups, with median age of 54 years and median Karnofsky performance status (KPS) of 80%. More than 80% of participants had failed two or more prior chemotherapy regimens ( $\geq$  second recurrence) and 20% had failed bevacizumab prior to study enrollment (Stupp, 2012).

Two hundred and thirty-seven patients were randomized in a 1:1 ratio to receive TTF therapy only (n=120) or BSC (n=117). The choice of chemotherapy regimens varied, reflecting local practice at each of the participating clinical centers (Stupp, 2012). Chemotherapy agents considered as BSC during the trial included platinum-based chemotherapy (i.e., carboplatin); nitrosureas; procarbazine; combination of procarbazine, lomustine and vincristine (PCV); temozolomide; and bevacizumab. For patients assigned to the TTF group, uninterrupted treatment was recommended, although patients were allowed to take treatment breaks of up to an hour, twice per day, for personal needs (e.g., shower). In addition, patients assigned to the TTF group were allowed to take 2–3 days off treatment at the end of each of 4-week period (which is the minimal required treatment duration for TTF therapy to reverse tumor growth). A period of 28 days of treatment with TTF was considered one full treatment course (Stupp, 2012).

The primary study endpoint in this RCT was overall survival (OS) (Stupp, 2012). Secondary endpoints included progression free survival at six months, time to progression (TTP), one-year survival rate, quality of life (QOL), and radiological response. Participants were seen in clinic monthly, and magnetic resonance imaging (MRI) was performed after 2, 4 and 6 months from initiation of treatment, with subsequent MRIs done according to local practice until disease progression. Medical follow-up continued for two months after disease progression. Monthly telephone interviews with the participants' caregivers were used to assess participant mortality rates (Stupp, 2012).

Ninety-seven percent (116) of 120 participants in the TTF group started treatment and 93 participants (78%) completed one cycle (4 weeks) of therapy. Discontinuation of TTF therapy occurred in 27 participants (22%) due to noncompliance or the inability to handle the device (Stupp, 2012). For each TTF treatment month, the median compliance was 86% (range 41-98%), which equaled a mean use of 20.6 hours per day. In the BSC group, 113 (97%) of the 117 assigned participants received chemotherapy and all except one individual completed a full treatment course. 21 participants (18%) in the BSC group did not return to the treating site and details on disease progression and toxicity were not available (Stupp, 2012).

This RCT did not reach its primary end-point of improved survival compared to active chemotherapy (Stupp, 2012). With a median follow-up of 39 months, 220 participants (93%) had died. Median survival was 6.6 months in the TTF group compared to 6.0 months in the BSC group (hazard ratio 0.86; 95% confidence interval [95% CI], 0.66 – 1.12;  $p = 0.27$ ). For both groups, one-year survival was 20%. The survival rates for 2- and 3-years were 8% and 4% for the TTF group versus 5% and 1% for the BSC group. Progression-free survival rate at six months was 21.4% in the TTF group, compared to 15.1% in the BSC group ( $p = 0.13$ ). Objective radiological responses (partial and complete response) were noted in 14 participants in the TTF group and 7 in the BSC group, with a calculated response rate of 14.0% (95% CI, 7.9 - 22.4%) compared to 9.6% (95% CI 3.9 – 18.8%), respectively. Sixteen percent of the TTF participants had grade 1 and 2 contact dermatitis on the scalp, which resolved with topical steroids. BSC participants experienced grade 2-4 events by organ system related to the pharmacologic activity of chemotherapy agents utilized; severe (grades 3 and 4) toxicity was observed in 3% of participants (Stupp, 2012).

Longitudinal QOL data were available in 63 participants (27%) (Stupp, 2012). There were no meaningful differences observed between the groups in the domains of global health and social functioning. However, cognitive, emotional, and role functioning favored TTF therapy, whereas physical functioning favored chemotherapy. Symptom scale analysis was in accordance to treatment-associated toxicity; appetite loss, diarrhea, constipation, nausea and vomiting were directly related to the chemotherapy administration. Increased pain and fatigue was reported in the chemotherapy-treated patients and not in the TTF group. Post-hoc

subgroup analyses of this trial data have been published in abstract form comparing outcomes of patients between both groups who had failed bevacizumab prior to study enrollment (Ram, 2010; Ram, 2011). Two very small case series have also been published of long-term survival (> six years) with TTF therapy (Rulseh, 2012; Vilano, 2013).

In summary, this RCT failed to demonstrate the primary endpoint of improved survival with TTF therapy in comparison to chemotherapy (Stupp, 2012; De Bonis, 2012). Limitations of the trial included a somewhat heterogeneous patient population, with participants included after progression of one or several lines of chemotherapy, as well as the use of different chemotherapy regimens in the control group. Another limitation is the absence of a placebo/supportive care arm. In the setting of advanced disease, the supportive care arm would have been useful to gauge the safety and efficacy of treatment for both groups of patients. Treatments used in the active control arm (best standard of care chemotherapy) in the recurrent disease setting have previously demonstrated limited efficacy, thus limiting the ability to determine the true treatment effect of TTF. Data from a trial of TTF versus placebo, or of TTF plus standard chemotherapy versus standard chemotherapy alone would therefore provide a better assessment of treatment efficacy. The latter study design is being used in an ongoing trial of TTF therapy in the treatment of newly diagnosed GBM patients.

A further limitation was high dropout rates in both groups. For example, over 20% of participants in the BSC group were lost at follow-up, and this degree of dropouts may have underestimated the toxicity evaluation in this group. Similarly, over 20% of participants in the TTF arm discontinued treatment within a few days due to noncompliance or inability to handle the device. This implies that compliance might be an issue with TTF as it requires the patient to continuously wear transducers on the shaved head and as a result. Finally, the number of patients who completed the QOL data was approximately one-quarter of total enrollment, and the self-reported QOL indicators may have been subject to bias due to the lack of blinding (Stupp, 2012; FDA, 2011). Therefore, due to the numerous methodologic limitations, evidence from this trial is not sufficient to demonstrate that TTF therapy results in improved health outcomes for patients with recurrent GBM.

### **Ongoing Clinical Trials**

Two manufacturer-sponsored studies on NovoTTF-100A System for treatment of GBM currently are listed at online site ClinicalTrials.gov. Post-approval study of NovoTTF-100A in recurrent GBM patients (NCT01756729)

This study is a post-market non-randomized, concurrent control study, designed to confirm that the efficacy of the NovoTTF-100A System in patients with recurrent GBM treated in a real life settings following FDA approval is comparable to that of BSC chemotherapy patients. This trial has the estimated enrollment of 486 adult patients across two US sites. The primary outcome measure is OS at five years of follow-up. This study is currently recruiting participants with the estimated completion date of January 2018.

Effect of NovoTTF-100A together with temozolomide in newly diagnosed GBM (NCT00916409).

The study is a subsequent prospective multinational RCT designed to test the efficacy and safety of the NovoTTF-100A System, as an adjuvant to the best standard of care in the treatment of newly diagnosed GBM patients. This trial has the estimated enrollment of 700 adult patients across 79 sites. Trial participants randomized to the intervention arm will be treated continuously with the NovoTTF-100A device, in addition to temozolomide chemotherapy; patients in the control arm will be treated with temozolomide, as the best known standard of care for GBM patients. The primary outcome measure is progression free survival at five years; the secondary outcome measure is OS at five years. This study is currently recruiting participants with the estimated completion date of April 2015.

TTF therapy using the NovoTTF-100A System is also being studied as a treatment for other solid tumors including non-small cell lung cancer (NCT01755624).

### **Summary**

Tumor-treating fields (TTF) therapy is a new noninvasive technology using electrical fields for treating recurrent glioblastoma. The available evidence consists of small case series and one randomized controlled superiority trial based on the FDA-approved device. This trial had numerous methodologic limitations and failed to demonstrate an improvement in overall survival or disease response. There were some differences reported in quality-of-life, but this data was limited by a low response rate for QOL measures. In addition, the best standard chemotherapy protocols reported in the randomized controlled trial may not reflect current practice, given the increased use of bevacizumab and temozolomide for treatment of patients with recurrent glioblastoma. No data

were available to address a comparison to other third-line treatment modalities (i.e., radiation, surgery, combination therapy).

Further evidence from high-quality trials is needed to assess the long term safety and efficacy of TTF. There are currently ongoing clinical trials of the TTF therapy including an ongoing post-marketing non-inferiority study that will provide additional data on outcomes of interest.

**Practice Guidelines and Position Statements**

The National Comprehensive Cancer Network (NCCN) in their clinical practice guidelines on Central Nervous Systems Tumors (Version 2, 2013) has a Category 2B recommendation to consider the use of TTF therapy for persons with local, diffuse or multiple recurrences of GBM ("Category 2B: Based upon lower-level evidence, there is NCCN consensus that the intervention is appropriate.") (NCCN, 2013). This recommendation was based on the RCT findings by Stupp and colleagues reported above.

**2014 Update**

A literature search conducted through July 2014 did not reveal any new information that would prompt a change in the coverage statement. The key identified literature is summarized below.

The FDA approval of the NovoTTF-100A system was based on a Phase III, multinational prospective RCT which was published in 2012 by Stupp et al. The Stupp et al study, which was sponsored and funded by the manufacturer of the device (NovoCure), compared TTF therapy (delivered by the NovoTTF-100A System) to the best standard of care chemotherapy (active control).<sup>3</sup> Twenty-eight clinical centers (across 7 countries) enrolled 237 adult participants with relapsed or progressive GBM, despite conventional radiotherapy. Other prior treatments may have included surgery and/or chemotherapy. Patient characteristics were balanced in both groups, with median age of 54 years and median Karnofsky performance status (KPS) of 80%. More than 80% of participants had failed 2 or more prior chemotherapy regimens ( $\geq$  second recurrence), and 20% had failed bevacizumab prior to study enrollment.

Wong et al published a subgroup analysis of the previously-described RCT to determine characteristics of responders and nonresponders in the treatment and active control groups (Wong, 2014). Tumor response was assessed by the Macdonald criteria. More patients in the TTF arm were considered responders (14/120) compared to 7/117 in the chemotherapy arm.) Median response time was longer for those in the TTF arm than the chemotherapy arm (7.3 months vs 5.6 months,  $P=0.0009$ ), and there was a strong correlation (Pearson's  $r$ ) between response and OS in the TTF arm ( $P = 0.0002$ ) but not in chemotherapy arm ( $P=0.29$ ). Compared with the chemotherapy arm, a higher proportion of responders in the TTF arm had a prior low-grade histology (36% vs 0%). These differences in treatment responder groups suggests that TTF may differentially benefit certain types of GBM; however, the small numbers of responders in both groups limits generalizations that can be drawn from this analysis.

Rulseh et al reported long-term ( $>7$  year) survival in 4 out of 20 patients with GBM who were treated with TTF, while Villano et al describe one patient with recurrent GBM who was tumor-free more than 6 years after treatment with TTF (Rulseh, 2012).

Since the approval of the NovoTTF device, additional case reports and small case series have been reported. Elzinga and Wong reported a case of a patient who demonstrated improved tumor response to bevacizumab in a patient who also received TTF therapy (Elzinga, 2014). Another case series ( $n=3$ ) suggested that adjusting the size of the electrical fields may improve response in cases of local tumor progression (Turner, 2014).

The use of TTF therapy has been described in a number of case series. However, without evidence from additional high quality comparative studies, these studies provide limited additional evidence about whether TTF therapy improves outcomes when compared to currently-available therapy for GBM

**Ongoing Clinical Trials**

A search of the online database ClinicalTrials.gov in June 2014 identified the following ongoing studies to evaluate the use of tumor treating fields therapy, including one randomized controlled trial (RCT) and 3 nonrandomized studies:

A phase 3, open-label randomized trial **Effect of NovoTTF-100A Together With Temozolomide in Newly Diagnosed Glioblastoma Multiforme (GBM) (NCT00916409)** – to compare the NovoTTF-100A as an adjuvant to the best current standard of care to standard of care alone in patients with newly-diagnosed GBM. Trial

participants randomized to the intervention arm will be treated continuously with the NovoTTF-100A device, in addition to temozolomide chemotherapy; patients in the control arm will be treated with temozolomide, as the best known standard of care for GBM patients. The primary outcome measure is PFS at 5 years; the secondary outcome measure is overall survival at 5 years. Enrollment is planned for 700 patients; the planned study completion date is January 2015.

A postmarket nonrandomized, concurrent control study, **Post-approval Study of NovoTTF-100A in Recurrent GBM Patients (NCT01756729)** –designed to confirm that the efficacy of the NovoTTF-100A System in patients with recurrent GBM treated in a real-life settings following FDA-approval is comparable to that of control chemotherapy patients. The primary outcome measure is overall survival at 5 years of follow-up. Enrollment is planned for 486 patients; the planned study completion date is January 2018.

A phase 2, nonrandomized, safety/efficacy study, **NovoTTF-100A With Bevacizumab (Avastin) in Patients With Recurrent Glioblastoma (NCT01894061)** –to evaluate the role of bevacizumab with the NovoTTF-100A in the treatment of glioblastoma. Enrollment is planned for 40 patients; the planned study completion date is December 2015.

A phase 2, nonrandomized, efficacy study, **NovoTTF Therapy in Treating Patients With Recurrent Glioblastoma Multiforme (NCT01954576)** – to evaluate NovoTTF in patients with recurrent or progressive tumor growth. Enrollment is planned for 30 subjects; the planned study completion date is May 2018.

### 2015 Update

A literature search was conducted using the MEDLINE database through July 2015. There was no new literature identified that would prompt a change in the coverage statement.

The following is a summary of the key identified literature.

A second post hoc analysis of the TTF EF-11 pivotal trial data was performed to evaluate OS rates among patients who completed at least 1 complete course of TTF or chemotherapy (Kanner, 2014). These investigators analyzed survival in what they referred to as a “modified ITT [intention to treat]” subgroup comprising 93 of 120 (78%) of the original TTF allocated group, versus 117 of 117 (100%) of the original chemotherapy allocated group. This exercise revealed median OS of 7.7 months in the TTF modified ITT (mITT) group compared with 5.9 months in the chemotherapy group (HR=0.69; 95% CI, 0.52 to 0.91; p=0.009). They also showed a trend relationship between proportion of patients with higher TTF compliance and median OS rates (p=0.039). The investigators suggest that TTF provides an OS benefit if used as intended in the FDA-approved label when compared with best chemotherapy. This post hoc analysis is limited as it was not prespecified in the study, includes only 78% of the original TTF allocated patients, and fails to control for noncompliance due to faster clinical deterioration of TTF recipients leading to treatment cessation.

A study published in late 2014 included OS data from 457 patients included in the Patient Registry Dataset (PRiDe), a postmarketing registry of all recurrent GBM patients who received NovoTTF therapy in a real-world, clinical practice setting in 91 centers in the United States between October 2011 and November 2013 (Mrugala, 2014). The median OS rate in the PRiDe clinical practice dataset was reported as significantly superior to that attained in the TTF EF-11 pivotal trial (9.6 months vs 6.6 months; HR=0.66, 95% CI, 0.05 to 0.86; p<0.001). One- and 2-year OS rates for TTF in PRiDe were significantly longer than those in the TTF group in the EF-11 trial (44% vs 20% at 1 year; 30% vs 9% at 2 years, respectively). The PRiDe investigators reported no novel or unexpected treatment-related adverse events compared with the EF-11 trial.

The National Comprehensive Cancer Network Central Nervous System Tumors guidelines (v.1.2015) (NCCN, 2015) has updated the recommendation for the treatment of recurrence of glioblastoma, with the option “consider alternating electric field therapy for glioblastomas” from a category 3 recommendation to a 2B recommendation.

### 2016 Update

A literature search conducted through July 2016 did not reveal any new information that would prompt a change in the coverage statement. The key identified literature is summarized below.

#### **TTF as an Adjunct to Standard Maintenance Care for GBM**

In 2015, Stupp et al published a planned interim analysis of a multicenter, open-label RCT that evaluated maintenance therapy with TTF for GBM (Stupp, 2015). This study enrolled patients with GBM who had completed standard treatment consisting of chemoradiotherapy, plus surgery if indicated. Patients were

randomized in a 2:1 fashion to receive either TTF plus temozolomide (vs temozolomide alone). At the time of the interim analysis, there were 210 patients randomized to TTF plus temozolomide and 105 patients randomized to temozolomide alone. The primary outcome was PFS analyzed by intention-to-treat; a secondary outcome was OS analyzed by per-protocol analysis.

Patients in the TTF group received continuous TTF delivered mainly in the home setting. Patients were trained on use of the device including changing the electrodes, and then treatment continued at home. Patients were encouraged to wear the device continuously, with the exception of short breaks to attend to personal needs. All patients were seen monthly for follow-up. MRI was performed every 2 months and QOL measures administered every 3 months. Tumor progression was adjudicated by a central review committee blinded to treatment group.

Planned interim analysis was performed at a median follow-up of 38 months (range, 18-60 months). Median PFS and median OS are summarized as:

Group Tumor Treatment Fields (TTF) + temozolomide; N= 210 (196 included in per-protocol analysis; progression-free survival (95% confidence interval); hazard ratio (98.7% confidence interval); overall survival (95% confidence interval);p hazard ratio

There were a total of 35 (11%) dropouts during the study, 14 (6.7%) of 210 patients in the TTF group and 21 (20%) of 105 in the temozolomide alone group. Adherence to treatment was defined as wearing the device for at least 18 hours a day, and 157 (75%) of 210 patients met this criteria for adherence. The number of cycles of treatment with temozolomide differed between groups. The TTF group received a median of 6 cycles compared with a median of 4 cycles for the temozolomide alone group. The most common side effect of treatment was local skin irritation, which occurred in 43% of patients treated with TTF.

## 2017 Update

A literature search conducted through July 2017 did not reveal any new information that would prompt a change in the coverage statement.

## 2018 Update

Annual policy review completed with a literature search using the MEDLINE database through June 2018. The key identified literature is summarized below.

## TTF THERAPY AS AN ADJUNCT TO STANDARD MAINTENANCE CARE FOR NEWLY DIAGNOSED GBM

### Randomized Controlled Trials

Stupp et al published results of the EF-14 multicenter, open-label phase 3 RCT that evaluated maintenance therapy with TTF for newly diagnosed GBM (Stupp, 2017). The trial included 695 patients from 83 sites who had supratentorial GBM and had completed standard treatment consisting of biopsy or surgical resection followed by radiotherapy and chemotherapy. A Karnofsky Performance Status (KPS) score of 70 or higher was an additional inclusion criterion to ensure independence in activities of daily living, and patients with rapidly progressing GBM following radiochemotherapy were excluded from the trial. Patients were randomized in a 2:1 fashion to TTF plus maintenance temozolomide or maintenance temozolomide alone.

All patients were seen monthly for follow-up. Quality of life (QOL) was assessed every 3 months, and magnetic resonance imaging (MRI) was performed every 2 months until tumor progression. Tumor progression on MRI was adjudicated by a central review committee blinded to treatment group. The primary outcome was progression-free survival (PFS), and the secondary outcome was overall survival (OS). The analysis was by intention-to-treat, including 26 patients from the control arm who crossed over to TTF following the planned interim analysis.

In 2014, an independent data and safety monitoring board concluded from the planned interim analysis that the trial met its predefined boundaries for success (improvement in PFS and OS) and recommended trial termination. The Food and Drug Administration approved the trial termination, and the trial was closed to recruitment with 695 of the planned 700 participants randomized. Control arm participants were allowed to cross over to the experimental treatment at this time. Stupp et al published the interim analysis, which the Food and Drug Administration considered for the 2015 expanded approval of Optune (Stupp, 2015). At the time of the interim analysis, data were available for 210 patients randomized to TTF plus temozolomide and 105 patients to temozolomide alone. Follow-up of the remainder of the 695 enrolled patients continued after enrollment was closed.

Results of the final analysis of the EF-14 trial were similar to the interim analysis. Both PFS and OS improved with the addition of TTF therapy to standard maintenance chemotherapy (ie, temozolomide). PFS increased by 2.7 mo ( $p<0.001$ ) and OS increased by 4.9 mo ( $p<0.001$ ) in the TTF group. The time to a decrease in mental function was 2.5 months longer with TTF therapy ( $p<0.01$ ).

There was a similar percentage of dropouts at the final analysis with 49 (11%) patients in the TTF group and 27 (12%) patients in the temozolomide alone group. More treatment cycles with temozolomide were administered in the TTF group (median, 6 for TTF group vs 5 for controls), a finding that is consistent with the longer PFS. Rates of adverse events were similar between the groups, including rates of seizures. In secondary analysis of patients who had not progressed, there was no reduction in health-related quality of life with TTF compared with temozolomide alone aside from "itchy skin" (Taphoorn, 2018). Interpretation of this result is limited by the low percentage of patients who completed the health-related quality of life assessments at follow-up (65.8% of the 655 patients alive at 3 months and 41.7% of the 473 patients alive at 12 months). A mixed-model analysis, which accounts for missing data, confirmed the results of the mean change from baseline analysis.

The major limitation of this trial is the lack of patient blinding to treatment assignment. However, PFS was assessed by investigators who were blinded to treatment and placebo effects on OS were expected to be minimal. Investigators considered it practically unfeasible (due to the heat and current of the TTF therapy) and ethically unacceptable to submit the control patients to repeated shaving of the head and continuous wear of a sham device over many months.

In summary, the final analysis of the EF-14 trial, which included 695 patients from 83 sites, found a statistically and clinically significant increase of 2.7 months in PFS and an increase of 4.9 months in OS with the addition of TTF therapy to standard maintenance therapy (ie, temozolomide) in patients with newly diagnosed GBM. There was no sham control, and patients were not blinded to treatment assignment, but PFS was assessed by blinded evaluators, and placebo effects on the objective measure of OS were likely to be minimal. There was no evidence of a negative impact of TTF therapy on health-related quality of life, except for itchy skin from the transducers.

**TTF THERAPY AS AN ADJUNCT OR ALTERNATIVE TO MEDICAL THERAPY FOR PROGRESSIVE OR RECURRENT GBM**

Results of a phase 3 multinational RCT (EF-11) published by Stupp et al, was the basis for the 2011 Food and Drug Administration approval of the NovoTTF-100A System (now called Optune) (Stupp, 2012). This trial compared TTF therapy alone with physician's choice medical therapy in 237 adults who had relapsed or progressive glioblastoma. Patients had failed conventional treatment with radiotherapy, chemotherapy, and/or surgery, and more than 80% of participants had failed 2 or more prior chemotherapy regimens. In this trial, the term chemotherapy also applied to targeted agents such as bevacizumab. Patient characteristics and performance of additional post-recurrence debulking surgery were similar in the 2 groups.

Participants were followed monthly, including laboratory tests. MRI images were evaluated at 2, 4, and 6 months from initiation of treatment, with subsequent MRIs performed according to local practice until disease progression. QOL questionnaires were completed every 3 months. Medical follow-up continued for 2 months after disease progression. Monthly telephone interviews with participants' caregivers were used to assess mortality rates. The primary end point was OS. Secondary end points included PFS, the percentage of patients with PFS at 6 months, time to progression, 1-year survival rate, QOL, and radiologic response. All end points were evaluated using intention-to-treat analysis.

The trial did not reach its primary end point of improved survival compared with active medical therapy. With a median follow-up of 39 months, 93% of patients had died. There was not a statistically significant difference in survival rates at 1, 2, and 3 years between groups. Patients in the TTF group did not, however, suffer the typical systemic side effects of chemotherapy. The most common adverse event in the TTF group was grade 1 and 2 contact dermatitis on the scalp, which resolved with topical corticosteroids and did not require treatment breaks. Control participants experienced grade 2, 3, or 4 events by organ system related to the pharmacologic activity of chemotherapy agents used. Hematologic events of grade 2 or greater were observed in 17% of chemotherapy patients compared with 3% of TTF patients. Gastrointestinal disorders of grade 2 or greater were identified in 17% of chemotherapy patients compared with 4% of TTF patients. Severe (grades 3-4) hematologic and gastrointestinal toxicity was observed in 7% of chemotherapy controls compared with 1% of the TTF group.

Longitudinal QOL data, available in 63 (27%) participants, showed no meaningful differences between groups for the domains of global health and social functioning. However, cognitive and emotional functioning domains favored TTF therapy. Symptom scale analysis was by treatment-associated toxicity; appetite loss, diarrhea, constipation, nausea, and vomiting were directly related to the chemotherapy administration.

The trial had a number of limitations that included lack of blinding and high loss to follow-up. Discontinuation of TTF therapy occurred in 22% of patients due to noncompliance or inability to handle the device, usually within the first few days. In the control group, 21 (18%) patients did not return to the treatment site, and details on disease progression and toxicity were not available. Longitudinal QOL could be analyzed only for 27% of patients who remained on study therapy for 3 months. The trial was designed as a superiority trial and did not provide adequate evidence of noninferiority.

**Nonrandomized Comparative Studies**

Kesari et al conducted a post hoc analysis of the EF-14 trial to evaluate the efficacy of TTF in patients who had the first recurrence (Kesari, 2017). Some patients in the temozolomide alone group crossed over to receive TTF plus chemotherapy after the first recurrence, resulting in 144 patients who received TTF fields plus chemotherapy and 60 patients who received chemotherapy alone for recurrent GBM. Patient characteristics and second-line treatments were well-balanced between the groups, with bevacizumab the most common second-line therapy. The median OS in patients treated with systemic therapy alone was 9.2 months. In comparison, the group of patients who received TTF therapy in addition to systemic therapy had a median OS of 11.8 months (p=0.043).

## Subject: Tumor Treatment Fields Therapy for Glioblastoma

THIS MEDICAL COVERAGE GUIDELINE IS NOT AN AUTHORIZATION, CERTIFICATION, EXPLANATION OF BENEFITS, OR A GUARANTEE OF PAYMENT, NOR DOES IT SUBSTITUTE FOR OR CONSTITUTE MEDICAL ADVICE. ALL MEDICAL DECISIONS ARE SOLELY THE RESPONSIBILITY OF THE PATIENT AND PHYSICIAN. BENEFITS ARE DETERMINED BY THE GROUP CONTRACT, MEMBER BENEFIT BOOKLET, AND/OR INDIVIDUAL SUBSCRIBER CERTIFICATE IN EFFECT AT THE TIME SERVICES WERE RENDERED. THIS MEDICAL COVERAGE GUIDELINE APPLIES TO ALL LINES OF BUSINESS UNLESS OTHERWISE NOTED IN THE PROGRAM EXCEPTIONS SECTION.

### DESCRIPTION:

Glioblastomas, also known as glioblastoma multiforme (GBM), are the most common form of malignant primary brain tumor in adults. They comprise approximately 15% of all brain and central nervous system tumors and more than 50% of all tumors that arise from glial cells. The peak incidence for GBM occurs between the ages of 45 and 70 years. GBMs are grade IV astrocytomas, and are often resistant to standard chemotherapy.

The primary treatment for GBM is debulking surgery to remove as much of the tumor as possible. At that time, some individuals may undergo implantation of the tumor cavity with a carmustine (bischloroethylnitrosourea [BCNU])–impregnated wafer. Depending on the individual’s physical condition, adjuvant radiotherapy, chemotherapy (typically temozolomide), or a combination of the 2 are sometimes given. After adjuvant therapy, some may undergo maintenance therapy with temozolomide.

No standard treatment exists for recurrent GBM. In those with disease that recurs after these initial therapies, additional debulking surgery may be used if recurrence is localized. Other treatment options for recurrent disease include various forms of systemic medications such as bevacizumab, bevacizumab plus chemotherapy (eg, irinotecan, BCNU/chloroethylnitrosourea [CCNU], temozolomide), temozolomide, nitrosourea, PCV (procarbazine, CCNU, vincristine), cyclophosphamide, and platinum-based agents. External beam radiotherapy (EBRT) also may be used to treat recurrent GBM. Response rates in recurrent disease are less than 10%, and progression-free survival rates at 6 months are less than 20%.

TTF therapy is a noninvasive technology that is intended to treat GBM on an outpatient basis using electrical fields. TTF therapy exposes cancer cells to alternating electric fields of low intensity and intermediate frequency, which are purported to both selectively inhibit tumor growth and reduce tumor angiogenesis. TTF are proposed to inhibit rapidly dividing tumor cells by 2 mechanisms, arrest of cell proliferation and destruction of cells while undergoing division.

TTF therapy via the Optune™ (formerly NovoTTF-100A System) System is delivered by a battery-powered, portable device that generates the fields via disposable electrodes that are noninvasively attached to the individual's shaved scalp over the site of the tumor. The device is used by the individual at home on a continuous basis for the duration of treatment, which can last for several months. The device is carried in a backpack or shoulder pack while carrying out activities of daily living.

Treatment planning software (eg, NovoTAL) is available and designed to be utilized prior to starting TTF treatment. NovoTAL is optional software that a physician can purchase and use to create individualized treatment maps. It is purported to allow the physician to individualize treatment by determining optimal placement of the transducer arrays, based on the individual's most recent magnetic resonance imaging (MRI) scan, head size and tumor location. It is performed in-office. Physicians are required to complete training and certification in order to use the NovoTAL System. The Optune™ device is available preset from Novocure. The device is preset to deliver TTF at a frequency of 200 kHz and is operated by the patient independently. It is monitored periodically by device specialists, who are available 24/7 to provide technical support to the patient, their family and physician.

## REGULATORY STATUS

The Optune™ (formerly NovoTTF-100A System) System was approved by the FDA in April 2011, as a stand-alone treatment for adults age 22 years or older with confirmed GBM that recurs or progresses after surgical and radiation options have been exhausted. On October 5, 2015 the FDA granted approval for use of Optune™ in combination with temozolomide to treat adults age 22 years or older with newly diagnosed, supratentorial GBM after maximal debulking surgery and completion of radiation therapy, together with concomitant standard of care chemotherapy.

## POSITION STATEMENT:

The use of tumor treatment fields therapy (TTF) to treat glioblastoma **meets the definition of medical necessity** when **ALL** of the following criteria are met:

- The device is FDA approved
- Age 22 or older
- There is histologically-confirmed supratentorial glioblastoma (also known as glioblastoma multiforme [GBM] or World Health Organization [WHO] grade IV astrocytoma)
- Initial treatment with debulking surgery or biopsy followed by chemoradiation with concomitant temozolomide and radiotherapy has been completed, with no documented tumor progression\*
- TTF is used in combination with temozolomide

- Karnofsky Performance Status score of 70 or higher, OR Eastern Cooperative Oncology Group (ECOG) performance status 0-1

\* Progression is defined as tumor growth greater than 25% compared to smallest measured tumor area, or the appearance of one or more new GBM lesions in the brain.

The use of tumor treatment fields therapy (TTF) to treat glioblastoma recurrence **meets the definition of medical necessity** when **ALL** of the following criteria are met:

- The device is FDA approved
- Age 22 or older
- There is histologically-confirmed recurrence of supratentorial glioblastoma (also known as glioblastoma multiforme [GBM] or World Health Organization [WHO] grade IV astrocytoma) following treatment with chemotherapy and/or radiation
- TTF is used as monotherapy

The use of tumor treatment fields therapy (TTF) for all other indications is considered **experimental or investigational**. There is insufficient clinical evidence in the peer-reviewed literature on this technology to support its safety, effectiveness, and long term effects on net health outcomes for other types of cancer.

The use of treatment planning software (eg, NovoTAL) for use with tumor treatment fields for any indication is considered **experimental or investigational**. Data in published medical literature are inadequate to permit scientific conclusions on long-term and net health outcomes.

## **BILLING/CODING INFORMATION:**

### **HCPCS Coding**

A4555	Electrode/transducer for use with electrical stimulation device, used for cancer treatment, replacement only
E0766	Electrical stimulation device, used for cancer treatment, includes all accessories, any type

## **REIMBURSEMENT INFORMATION:**

Refer to section entitled [\*\*POSITION STATEMENT\*\*](#).

## **PROGRAM EXCEPTIONS:**

**Federal Employee Program (FEP):** Follow FEP guidelines.

**State Account Organization (SAO):** Follow SAO guidelines.

**Medicare Advantage products:** The following Durable Medical Equipment Regional Carrier (DMERC) Local Coverage Determination (LCD) was reviewed on the last guideline reviewed date: Tumor Treatment Field Therapy (TTFT) (L34823), located at [cgsmedicare.com](https://www.cms.gov/medicare/coverage/determinations/lcds/l34823)

## DEFINITIONS:

<b>Eastern Cooperative Oncology Group (ECOG) Performance Status:</b>	
A scale used to determine an individual's level of functioning:	
0	Fully active, able to carry on all pre-disease performance without restriction
1	Restricted in physically strenuous activity but ambulatory and able to carry out work of a light or sedentary nature, e.g., light house work, office work
2	Ambulatory and capable of all self-care but unable to carry out any work activities. Up and about more than 50% of waking hours
3	Capable of only limited self-care, confined to bed or chair more than 50% of waking hours
4	Completely disabled. Cannot carry on any self-care. Totally confined to bed or chair
5	Dead

<b>Karnofsky Performance Status Score:</b>	
A scale used by healthcare providers to quickly evaluate how an individual is feeling on any given day:	
100	Normal, no complaints
90	Able to carry on normal activities. Minor signs or symptoms of disease
80	Normal activity with effort
70	Care for self. Unable to carry on normal activity or to do active work
60	Requires occasional assistance, but able to care for most of his needs
50	Requires considerable assistance and frequent medical care
40	Disabled. Requires special care and assistance

30	Severly disabled. Hospitalisation indicated though death nonimminent
20	Very sick. Hospitalisation necessary. Active supportive treatment necessary
10	Moribund
0	Dead

Populations	Interventions	Comparators	Outcomes
Individuals: • With newly diagnosed glioblastoma multiforme on maintenance therapy after initial treatment	Interventions of interest are: • Tumor treating fields therapy as an adjunct to standard maintenance therapy	Comparators of interest are: • Standard maintenance therapy alone	Relevant outcomes include: • Overall survival • Disease-specific survival • Quality of life • Treatment-related morbidity
Individuals: • With progressive or recurrent glioblastoma multiforme	Interventions of interest are: • Tumor treating fields therapy as an adjunct or alternative to medical therapy	Comparators of interest are: • Standard medical therapy	Relevant outcomes include: • Overall survival • Disease-specific survival • Quality of life • Treatment-related morbidity

**DESCRIPTION**

Glioblastoma multiforme (GBM) is the most common and deadly malignant brain tumor. It has a very poor prognosis and is associated with low quality of life during of treatment. Tumor treatment fields (TTF) therapy is a new, noninvasive technology intended to treat glioblastoma using alternating electric fields.

**OBJECTIVE**

The objective of this policy is to determine whether the use of tumor treating fields therapy improves the net health outcome for patients with solid tumors including glioblastoma multiforme.

**BACKGROUND****Glioblastoma Multiforme**

Glioblastomas, also known as glioblastoma multiforme (GBM), are the most common form of malignant primary brain tumor in adults.<sup>1</sup> GBMs are grade IV astrocytomas, a rapidly progressing and deadly type of glial cell tumor that is often resistant to standard medical therapy (eg, bevacizumab, chemotherapy). Together, anaplastic astrocytomas and glioblastomas comprise approximately 38% of all brain and central nervous system tumors.<sup>1</sup> The peak incidence for GBM occurs between the ages of 45 and 70 years, with a median age at diagnosis of 64 years. Glioblastomas have the lowest survival rate of any central nervous system tumor; in one report, about a third of patients survived to 1 year, and the 5-year survival rate was around 5%.<sup>2</sup>

Clinical Context and Therapy Purpose

The purpose of alternating electrical field therapy, more commonly known as tumor treating fields (TTF) therapy, is to provide a treatment option that is better than existing therapies for GBM. TTF has been investigated as an adjunct to temozolomide for the treatment of newly diagnosed GBM and as an alternative or adjunct to medical therapy for progressive or recurrent GBM.

Treatment of Newly Diagnosed GBM

The primary treatment for patients newly diagnosed with GBM is to resect the tumor to confirm a diagnosis while debulking the tumor to relieve symptoms of increased intracranial pressure or compression. If total resection is not feasible, subtotal resection and open biopsy are options. During surgery, some patients may undergo implantation of the tumor cavity with a carmustine (bis-chloroethylnitrosourea) impregnated wafer. Due to the poor efficacy of local treatment, postsurgical treatment with adjuvant radiotherapy, chemotherapy (typically temozolomide), or a combination of these 2 therapies is recommended. After adjuvant therapy, patients may undergo maintenance therapy with temozolomide. Maintenance temozolomide is given for 5 days of every 28-day cycle for 6 cycles. Response and overall survival rates with temozolomide are higher in patients who have O<sup>6</sup>-methylguanine-DNA methyltransferase (*MGMT*) gene promoter methylation.

Prognostic factors for therapy success are age, histology, performance status or physical condition of the patient, and extent of resection. National Comprehensive Cancer Network recommendations include patient age and Karnofsky Performance Status score as important determinants of postsurgical treatment choice (see the Supplemental Information section).<sup>3</sup> For patients with good performance status, the most aggressive treatment (standard radiotherapy [RT] plus temozolomide) is recommended. For patients with poor performance status, only single treatment cycles or even palliative or supportive care are recommended. Hypofractionated RT is indicated for patients with poor performance status because it is better tolerated, and more patients are able to complete RT.

Treatment of GBM is rarely curative, and tumors will recur essentially all patients.

#### Treatment of Recurrent GBM

When disease recurs, additional debulking surgery may be used if the recurrence is localized. Due to radiation tolerances, re-radiation options for patients with recurrent GBM who have previously received initial external-beam radiotherapy are limited. There is no standard adjunctive treatment for recurrent GBM. Treatment options for recurrent disease include various forms of systemic medications such as the antivascular endothelial growth factor drug bevacizumab, alkylating agents such as nitrosoureas (eg, lomustine, carmustine), or retreatment with temozolomide. Medical therapy is associated with side effects that include hematologic toxicity, headache, loss of appetite, nausea, vomiting, and fatigue. Response rates in recurrent disease are less than 10%, and the progression-free survival rate at 6 months is less than 20%.<sup>4</sup> There is a need for new treatments that can improve survival in patients with recurrent GBM or reduce the side effects of treatment while retaining survival benefits.

The questions addressed in this evidence review are:

- Does TTF, when used as an adjunct to maintenance medical therapy in patients with newly diagnosed GBM, improve the net health outcome?
- Does TTF, when used as an adjunct to medical therapy in patients with recurrent GBM, improve the net health outcome?
- Does TTF, when used as an alternative to medical therapy in patients with recurrent GBM, improve the net health outcome?

The following PICOTS were used to select literature to inform this review.

#### Patients

The relevant populations of interest are patients who have newly diagnosed GBM with good performance status or patients with recurrent GBM with good performance status. Newly diagnosed patients would have undergone initial treatment with surgery, RT, and chemotherapy and be receiving maintenance chemotherapy.

### Interventions

TTF therapy is a noninvasive technology intended to treat GBM on an outpatient basis and at home using electrical fields.<sup>4-6</sup> TTF therapy exposes rapidly dividing cancer cells to electric fields of low intensity and intermediate frequency (200 kHz) that alternate in perpendicular orientation. TTF therapy is proposed to inhibit tumor growth by 2 mechanisms: the arrest of cell proliferation by causing microtubule misalignment in the mitotic spindle of rapidly dividing tumor cells and apoptosis due to movement of macromolecules and organelles during telophase.<sup>5,6</sup> Preclinical studies have indicated that the electric fields may also make the cells more susceptible to chemotherapy.

Optune (formerly NovoTTF-100A System) is the only legally marketed TTF delivery system available in the United States. The portable, battery-powered device is carried in a backpack or shoulder pack while carrying out activities of daily living. For the treatment of glioblastoma, 4 disposable transducer arrays with insulated electrodes are applied to **the patient's shaved head. The transducer array layout is typically determined using specialized software. The patient's scalp is re-shaved** and the transducer arrays replaced twice a week by the patient, caregiver, or device technician. The device is worn for up to 24 hours a day for the duration of treatment, except for brief periods for personal hygiene and 2 to 3 days at the end of each month. The minimum daily treatment is 18 hours. The minimum duration of treatment is 1 month, with the continuation of treatment available until recurrence.

### Comparators

The following practice is currently being used to make decisions about newly diagnosed GBM: maintenance chemotherapy with temozolomide alone.

The following practices are currently being used to make decisions about recurrent GBM: medical therapy.

TTF therapy might also be compared with palliative or supportive care, where survival rarely exceeds 3 to 5 months.<sup>4</sup>

### Outcomes

The general outcomes of interest are whether TTF improves survival or quality of life during treatment and, because most GBMs recur, the time to tumor recurrence. Measures of cognitive status and quality of life measures are also of interest to determine whether TTF alters the decline in cognition and quality of life that occur with GBM. Also, adverse events of treatment such as side effects of chemotherapy and the possibility of seizures need to be assessed.

### Timing

Due to the rapid progression of GBM, the time of interest for both progression-free survival and overall survival is months.

Setting

The setting is outpatient care by an oncologist or neuro-oncologist.

**REGULATORY STATUS**

In April 2011, the NovoTTF-100A™ System (Novocure; assigned the generic name of TTF) was approved by the U.S. Food and Drug Administration (FDA) through the premarket approval process.<sup>7</sup> The FDA-approved label reads as follows: **"The NovoTTF-100A System is intended as a treatment for adult patients (22 years of age or older) with confirmed GBM, following confirmed recurrence in an upper region of the brain (supratentorial) after receiving chemotherapy. The device is intended to be used as a stand-alone treatment and is intended as an alternative to standard medical therapy for recurrent GBM after surgical and radiation options have been exhausted."**

In September 2014, FDA approved Novocure's request for a product name change from NovoTTF-110A System to Optune®.<sup>8</sup>

In October 2015, FDA expanded the indication for Optune® in combination with temozolomide to include newly diagnosed GBM.<sup>9</sup> The device was granted priority review status in May 2015 because there was no legally marketed alternative device available for the treatment of newly diagnosed GBM, a life-threatening condition. In July 2016, a smaller, lighter version of the Optune® device, called the Optune® System (NovoTTF-200A System), received FDA approval.

The FDA-approved label for newly diagnosed GBM reads as follows: **"This device is indicated as treatment for adult patients (22 years of age or older) with histologically-confirmed glioblastoma multiforme (GBM). Optune™ with temozolomide is indicated for the treatment of adult patients with newly diagnosed, supratentorial glioblastoma following maximal debulking surgery and completion of radiation therapy together with concomitant standard of care chemotherapy."**

FDA product code: NZK.

**POLICY**

- A. Tumor treating fields therapy to treat glioblastoma multiforme is considered **medically necessary** as an adjunct to standard maintenance therapy with temozolomide in patients with newly diagnosed glioblastoma multiforme following initial treatment with surgery, radiotherapy, and/or chemotherapy under the following conditions:
1. **Adult patients  $\geq 18$  years** of age
  2. Supratentorial tumor
  3. **Karnofsky Performance Status score  $\geq 70\%$**
  4. Patient understands device use, including the requirement for a shaved head, and is willing to comply with use criteria according to the Food and Drug Administration label (see Policy Guidelines).
- B. Tumor treating fields therapy is considered **experimental / investigational** in all other conditions, including but not limited to, the following situations:
1. As an adjunct to standard medical therapy (eg, bevacizumab, chemotherapy) for patients with progressive or recurrent glioblastoma multiforme
  2. As an alternative to standard medical therapy for patients with progressive or recurrent glioblastoma multiforme
  3. For brain metastases
  4. For cancer in areas other than the brain.

**Policy Guidelines**

1. Progression was defined in the EF-14 trial (Stupp et al [2015, 2017]) according to the MacDonald criteria (tumor growth  $>25\%$  compared with the smallest tumor area measured in the patient during the trial or appearance of 1 or more new tumors in the brain that are diagnosed radiologically as glioblastoma multiforme).
2. The Food and Drug Administration label includes the following notices:
  - a. Patients should use Optune for at least 18 hours a day to get the best response to treatment
  - b. Patients should finish at least 4 full weeks of therapy to get the best response to treatment. Stopping treatment before 4 weeks lowers the chances of a response to treatment.

## **RATIONALE**

The literature update was performed through April 5, 2018.

Evidence reviews assess the clinical evidence to determine whether the use of a technology improves the net health outcome. Broadly defined, health outcomes are length of life, quality of life, and ability to function—including benefits and harms. Every clinical condition has specific outcomes that are important to patients and to managing the course of that condition. Validated outcome measures are necessary to ascertain whether a condition improves or worsens; and whether the magnitude of that change is clinically significant. The net health outcome is a balance of benefits and harms.

To assess whether the evidence is sufficient to draw conclusions about the net health outcome of a technology, 2 domains are examined: the relevance and the quality and credibility. To be relevant, studies must represent one or more intended clinical use of the technology in the intended population and compare an effective and appropriate alternative at a comparable intensity. For some conditions, the alternative will be supportive care or surveillance. The quality and credibility of the evidence depend on study design and conduct, minimizing bias and confounding that can generate incorrect findings. The randomized controlled trial (RCT) is preferred to assess efficacy; however, in some circumstances, nonrandomized studies may be adequate. RCTs are rarely large enough or long enough to capture less common adverse events and long-term effects. Other types of studies can be used for these purposes and to assess generalizability to broader clinical populations and settings of clinical practice.

For this review, 3 indications are evaluated: (1) tumor treating fields (TTF) as an adjunct to maintenance chemotherapy in newly diagnosed patients following initial treatment with surgery, radiotherapy and chemotherapy and (2) TTF as an adjunct or (3) alternative to medical therapy (eg, bevacizumab, chemotherapy) in progressive or recurrent glioblastoma multiforme (GBM).

### **Study Selection**

The PICOTS was used to select relevant studies.

- To assess efficacy outcomes, comparative controlled prospective trials were sought, with a preference for RCTs.
- To assess longer term outcomes and adverse events, single-arm studies that capture longer periods of follow-up and/or larger populations were sought.
- Within each category of study design, studies with larger sample size studies and longer duration were sought.

### **TTF Therapy as an Adjunct to Standard Maintenance Care for Newly Diagnosed GBM** **Randomized Controlled Trials**

Stupp et al (2017) published results of the EF-14 multicenter, open-label phase 3 RCT that evaluated maintenance therapy with TTF for newly diagnosed GBM.<sup>10</sup> The trial included 695 patients from 83 sites who had supratentorial GBM and had completed standard treatment consisting of biopsy or surgical resection followed by radiotherapy and chemotherapy (see Table 1). A Karnofsky Performance Status (KPS) score of 70 or higher was an additional inclusion criterion to ensure independence in activities of daily living, and patients with rapidly progressing GBM following radiochemotherapy were excluded from the trial. Patients were randomized in a 2:1 fashion to TTF plus maintenance temozolomide or maintenance temozolomide alone.

All patients were seen monthly for follow-up. Quality of life (QOL) was assessed every 3 months, and magnetic resonance imaging (MRI) was performed every 2 months until tumor progression. Tumor progression on MRI was adjudicated by a central review committee blinded to treatment group. The primary outcome was progression-free survival (PFS), and the secondary outcome was overall survival (OS). The analysis was by intention-to-treat, including 26 patients from the control arm who crossed over to TTF following the planned interim analysis.

In 2014, an independent data and safety monitoring board concluded from the planned interim analysis that the trial met its predefined boundaries for success (improvement in PFS and OS) and recommended trial termination. The Food and Drug Administration approved the trial termination, and the trial was closed to recruitment with 695 of the planned 700 participants randomized. Control arm participants were allowed to cross over to the experimental treatment at this time. The interim analysis, which the Food and Drug Administration considered for the 2015 expanded approval of Optune, was published by Stupp et al (2015).<sup>11</sup> At the time of the interim analysis, data were available for 210 patients randomized to TTF plus temozolomide and 105 patients to temozolomide alone. Follow-up of the remainder of the 695 enrolled patients continued after enrollment was closed.

**Table 1.** Key Randomized Controlled Trial Characteristics for Newly Diagnosed Glioblastoma

Study; Trial	Countries	Sites	Dates	Participants	Interventions	
					Active	Comparator
Stupp et al (2017) <sup>10</sup> ; EF-14	U.S., E.U., South Korea, Israel	83	2009-2016	695 newly diagnosed with GBM and treated by radiochemotherapy <b>KPS score ≥70</b>	TTF >18 h/d plus maintenance temozolomide (n=466)	Maintenance temozolomide alone (5 d every 28 d for 6 cycles) (n=229)

GBM: glioblastoma multiforme; h/d: hours per day; KPS: Karnofsky Performance Status; TTF: tumor treatment fields.

Results of the final analysis of the EF-14 trial were similar to the interim analysis and are shown in Table 2. Both PFS and OS improved with the addition of TTF therapy to standard maintenance chemotherapy (ie, temozolomide). PFS increased by 2.7 mo ( $p<0.001$ ) and OS increased by 4.9 mo ( $p<0.001$ ) in the TTF group. The time to a decrease in mental function was 2.5 months longer with TTF therapy ( $p<0.01$ ).

There was a similar percentage of dropouts at the final analysis—with 49 (11%) patients in the TTF group and 27 (12%) patients in the temozolomide alone group. More treatment cycles with temozolomide were administered in the TTF group (median, 6 for TTF group vs 5 for controls), a finding that is consistent with the longer PFS. Rates of adverse events were similar between the groups, including rates of seizures. In secondary analysis of patients who had not progressed, there was no reduction in health-related quality of life with TTF compared with temozolomide **alone aside from “itchy skin”**.<sup>12</sup> Interpretation of this result is limited by the low percentage of patients who completed the health-related quality of life assessments at follow-up (65.8% of the 655 patients alive at 3 months and 41.7% of the 473 patients alive at 12 months). A mixed-model analysis, which accounts for missing data, confirmed the results of the mean change from baseline analysis.

**Table 2.** Key Randomized Controlled Trial Results for Newly Diagnosed Glioblastoma

Study	Final N (%)	Median PFS (95% CI), mo	Median OS (95% CI), mo	Systemic Adverse Events, n (%)	Seizures, n (%)	Time to 6-Point Decline in MMSE Score (95% CI), mo
Stupp et al (2017) <sup>10</sup>						
TTF + temozolomide	417 (89)	6.7 (6.1 to 8.1)	20.9 (19.3 to 22.7)	218 (48)	26 (6)	16.7 (14.7 to 19.0)
Temozolomide alone	202 (88)	4.0 (3.8 to 4.4)	16.0 (14.0 to 18.4)	94 (44)	13 (6)	14.2 (12.7 to 17.0)
HR (95% CI)		0.63 (0.52 to 0.76)	0.63 (0.53 to 0.76)			0.79 (0.66 to 0.95)
P value		<0.001	<0.001	0.58		0.01

CI: confidence interval; HR: hazard ratio; MMSE: Mini-Mental State Examination; OS: overall survival; PFS: progression-free survival; TTF: tumor treatment fields.

Tables 3 and 4 display notable gaps identified in this trial, the major limitation is the lack of patient blinding to treatment assignment. However, PFS was assessed by investigators who were blinded to treatment and placebo effects on OS were expected to be minimal. Investigators considered it practically unfeasible (due to the heat and current of the TTF therapy) and ethically unacceptable to submit the control patients to repeated shaving of the head and continuous wear of a sham device over many months.

<sup>d</sup> Data Completeness key: 1. High loss to follow-up or missing data; 2. Inadequate handling of missing data; 3. High number of crossovers; 4. Inadequate handling of crossovers; 5. Inappropriate exclusions; 6. Not intent to treat analysis (per protocol for noninferiority trials).

<sup>e</sup> Power key: 1. Power calculations not reported; 2. Power not calculated for primary outcome; 3. Power not based on clinically important difference.

<sup>f</sup> Statistical key: 1. Analysis is not appropriate for outcome type: (a) continuous; (b) binary; (c) time to event; 2. Analysis is not appropriate for multiple observations per patient; 3. Confidence intervals and/or p values not reported; 4. Comparative treatment effects not calculated.

### Section Summary: TTF Therapy as an Adjunct to Standard Maintenance Care for Newly Diagnosed GBM

The final analysis of the EF-14 trial, which included 695 patients from 83 sites, found a statistically and clinically significant increase of 2.7 months in PFS and an increase of 4.9 months in OS with the addition of TTF therapy to standard maintenance therapy (ie, temozolomide) in patients with newly diagnosed GBM. There was no sham control, and patients were not blinded to treatment assignment, but PFS was assessed by blinded evaluators, and placebo effects on the objective measure of OS were likely to be minimal. There was no evidence of a negative impact of TTF therapy on health-related quality of life, except for itchy skin from the transducers.

### **TTF Therapy as an Adjunct or Alternative to Medical Therapy for Progressive or Recurrent GBM**

#### Randomized Controlled Trials

The 2011 Food and Drug Administration approval of the NovoTTF-100A System (now called Optune) was based on a phase 3 multinational RCT (EF-11), results of which were published by Stupp et al (2012).<sup>4</sup> **This trial compared TTF therapy alone with physician's choice medical therapy** in 237 adults who had relapsed or progressive glioblastoma (see Table 5). Patients had failed conventional treatment with radiotherapy, chemotherapy, and/or surgery, and more than 80% of participants had failed 2 or more prior chemotherapy regimens. In this trial, the term chemotherapy also applied to targeted agents such as bevacizumab. Patient characteristics and performance of additional post-recurrence debulking surgery were similar in the 2 groups.

**Table 5.** Summary of Key Randomized Controlled Trial Characteristics for Progressive or Recurrent Glioblastoma

Study; Trial	Countries	Sites	Dates	Participants	Interventions	
					Active	Comparator
Stupp et al (2012) <sup>4</sup> ; EF-11	U.S., E.U., Israel	28	1987-2013	237 adults with relapsed or progressive supratentorial glioblastoma KPS score $\geq 70\%$	120 patients treated with TTF alone, 93 (78%) completed 1 cycle	117 patients treated with physician's choice of medical therapy <sup>a</sup>

EU: European Union; KPS: Karnofsky Performance Status; TTF: tumor treating fields.

<sup>a</sup> Medical therapy included bevacizumab, irinotecan, nitrosoureas, platinum-based chemotherapy (ie, carboplatin); temozolomide; or a combination of procarbazine, chloroethyl ether, and vincristine.

Participants were followed monthly, including laboratory tests. MRI images were evaluated at 2, 4, and 6 months from initiation of treatment, with subsequent MRIs performed according to local practice until disease progression. QOL questionnaires were completed every 3 months. Medical follow-up continued for 2 months after disease progression. Monthly telephone interviews with participants' caregivers were used to assess mortality rates. The primary end point was OS. Secondary end points included PFS, the percentage of patients with PFS at 6 months, time to progression, 1-year survival rate, QOL, and radiologic response. All end points were evaluated using intention-to-treat analysis.

The trial did not reach its primary end point of improved survival compared with active medical therapy (see Table 6). With a median follow-up of 39 months, 93% of patients had died. There

was not a statistically significant difference in survival rates at 1, 2, and 3 years between groups. Patients in the TTF group did not, however, suffer the typical systemic side effects of chemotherapy. The most common adverse event in the TTF group was grade 1 and 2 contact dermatitis on the scalp, which resolved with topical corticosteroids and did not require treatment breaks. Control participants experienced grade 2, 3, or 4 events by organ system related to the pharmacologic activity of chemotherapy agents used. Hematologic events of grade 2 or greater were observed in 17% of chemotherapy patients compared with 3% of TTF patients. Gastrointestinal disorders of grade 2 or greater were identified in 17% of chemotherapy patients compared with 4% of TTF patients. Severe (grades 3-4) hematologic and gastrointestinal toxicity was observed in 7% of chemotherapy controls compared with 1% of the TTF group.

Longitudinal QOL data, available in 63 (27%) participants, showed no meaningful differences between groups for the domains of global health and social functioning. However, cognitive and emotional functioning domains favored TTF therapy. Symptom scale analysis by treatment-associated toxicity; appetite loss, diarrhea, constipation, nausea, and vomiting were directly related to the chemotherapy administration.

The trial had a number of limitations (see Tables 7 and 8), that included lack of blinding and high loss to follow-up. Discontinuation of TTF therapy occurred in 22% of patients due to noncompliance or inability to handle the device, usually within the first few days. In the control group, 21 (18%) patients did not return to the treatment site, and details on disease progression and toxicity were not available. Longitudinal QOL could be analyzed only for 27% of patients who remained on study therapy for 3 months. The trial was designed as a superiority trial and did not provide adequate evidence of noninferiority.

**Table 6.** Summary of Key Randomized Controlled Trial Results for Recurrent or Progressive Glioblastoma

### Nonrandomized Comparative Studies

Kesari et al (2017) conducted a post hoc analysis of the EF-14 trial (see Stupp et al [2017] above) to evaluate the efficacy of TTF in patients who had the first recurrence.<sup>13</sup> Some patients in the temozolomide alone group crossed over to receive TTF plus chemotherapy after the first recurrence, resulting in 144 patients who received TTF fields plus chemotherapy and 60 patients who received chemotherapy alone for recurrent GBM (see Table 9). Patient characteristics and second-line treatments were well-balanced between the groups, with bevacizumab the most common second-line therapy. The median OS in patients treated with systemic therapy alone was 9.2 months (see Table 10). In comparison, the group of patients who received TTF therapy in addition to systemic therapy had a median OS of 11.8 months ( $p=0.043$ ).

A registry study published Mrugala et al (2014) assessed OS data from patients who received NovoTTF therapy in a real-world, clinical practice setting (see Table 9).<sup>14</sup> Concurrent treatment was not captured in the registry, and it is possible that some patients received combination therapy. Median OS in the PRiDe clinical practice dataset (9.6 mo) was reported as superior to that attained in the EF-11 pivotal trial (6.6 mo,  $p<0.001$ ) (see Table 10). More patients in the PRiDe registry were treated for first recurrence (33% vs 9%), and more had received bevacizumab as prior therapy (55% vs 19%). The PRiDe investigators reported no novel or unexpected treatment-related adverse events compared with the EF-11 trial.

P value	<0.001	9

CI: confidence interval; OS: overall survival; TTF: tumor treating fields.

Post hoc analyses of the EF-11 pivotal trial have been reported. Wong et al (2014) published a subgroup analysis to determine characteristics of responders and nonresponders in the active treatment and active treatment control.<sup>15</sup> They found that responders had a lower grade of histology and lower daily dexamethasone use than nonresponders. A second post hoc analysis by Kanner et al (2014) of the EF-11 pivotal trial data was performed to evaluate OS among patients who finished at least 1 complete course of TTF or chemotherapy.<sup>16</sup> The investigators reported that median OS was 7.7 months in the TTF group compared with 5.9 months in the chemotherapy group ( $p=0.009$ ). These post hoc analyses are considered to be hypothesis-generating.

#### *Section Summary: TTF Therapy as an Adjunct or Alternative to Chemotherapy for Progressive or Recurrent GBM*

The single RCT for TTF as an alternative to chemotherapy reported that outcomes following TTF therapy were similar to outcomes following standard chemotherapy. However, this RCT is not sufficient to permit conclusions on the efficacy of the device. The noninferiority of TTF compared with chemotherapy might be considered a sufficient health benefit, if TTF reduced treatment toxicity. However, because the trial was not designed as a noninferiority trial no inferences of **noninferiority compared with chemotherapy can be made. Physician's choice therapy during the** trial was heterogenous, although analysis indicated that survival was not affected by choice of chemotherapy. More patients in the TTF group than in the control group did not complete the treatment course. The number of patients who contributed QOL data was approximately one-quarter of total enrollment, and the self-reported QOL indicators might have been subject to bias due to the lack of blinding.

A nonrandomized post hoc evaluation of the EF-14 trial suggests that TTF may improve survival when combined with chemotherapy for recurrent GBM. This analysis should be considered hypothesis-generating, and further study in high-quality RCTs is needed.

### **SUMMARY OF EVIDENCE**

For individuals who have newly diagnosed GBM on maintenance therapy after initial treatment who receive TTF therapy as an adjunct to standard maintenance therapy, the evidence includes an RCT. Relevant outcomes include overall survival, disease-specific survival, symptoms, functional outcomes, quality of life, and treatment-related morbidity. The EF-14 trial found a significant increase of 2.7 months in progression-free survival and an increase of 4.9 months in overall survival with the addition of TTF therapy to standard maintenance therapy (ie, temozolomide) in patients with newly diagnosed GBM. Although patients were not blinded to treatment assignment, progression-free survival was assessed by blinded evaluators, and the placebo effects on the objective measure of overall survival are expected to be minimal. This technology represents a clinically significant option in the treatment of patients with GBM, for whom options are limited. The evidence is sufficient to determine that the technology results in a meaningful improvement in the net health outcome.

For individuals who have progressive or recurrent GBM who receive TTF therapy as an adjunct or alternative to standard medical therapy, the evidence includes an RCT and nonrandomized comparative studies. Relevant outcomes are overall survival, disease-specific survival, quality of life, and treatment-related morbidity. The single RCT evaluating TTF therapy for recurrent GBM did not show superiority of TTF therapy for the primary outcome (overall survival) compared with **physicians' choice chemotherapy. Because no serious adverse effects have been identified with** TTF therapy, this raises the possibility that treatment with TTF might reduce the toxicity associated with treatment for recurrent GBM. A reduction in chemotherapy-associated toxicity without loss of efficacy would be considered a net health benefit. However, this RCT is not sufficient to permit conclusions on the efficacy of the device. Because the trial was not designed as a noninferiority trial, no inferences of noninferiority compared with chemotherapy can be made. Also, quality of life assessment was measured in an insufficient number of patients to reach firm conclusions on differences in quality of life between TTF therapy and medical treatment. The highest quality study of TTF combined with medical treatment for recurrent GBM is a post hoc analysis of the EF-14 trial. A high-quality, prospective RCT is needed. The evidence is insufficient to determine the effects of the technology on health outcomes.

### **CLINICAL INPUT FROM PHYSICIAN SPECIALTY SOCIETIES AND ACADEMIC MEDICAL CENTERS**

While the various physician specialty societies and academic medical centers may collaborate with and make recommendations during this process, through the provision of appropriate reviewers, input received does not represent an endorsement or position statement by the physician specialty societies or academic medical centers, unless otherwise noted.

In response to requests, input was received from 3 physician specialty societies (one of which provided 6 responses and 2 of which provided 1 response each) and 1 academic medical center (total of 9 individual responses) while this policy was under review in 2016. There was majority support, but not consensus, for the use of tumor treatment fields therapy as an adjunct to maintenance treatment following initial therapy for glioblastoma multiforme. There was mixed

support for the use of tumor treatment fields as an alternative to chemotherapy in advanced or recurrent glioblastoma multiforme.

### PRACTICE GUIDELINES AND POSITION STATEMENTS

National Comprehensive Cancer Network guidelines on central nervous system cancers (v.1.2018) include recommendations for the treatment of glioblastoma (see Table 11).<sup>3</sup> For the initial treatment of patients with glioblastoma with good performance status and either methylated or unmethylated or indeterminate O<sup>6</sup>-methylguanine-DNA methyltransferase promotor status, treatment with standard brain radiotherapy plus concurrent temozolomide and adjuvant temozolomide plus alternating electric field therapy is a category 1 recommendation. Alternating electric currents therapy is only an option for patients with supratentorial disease. Consideration of alternating electric field therapy for recurrent glioblastoma is a category 2B recommendation.

**Table 11.** Guidelines for Adjuvant Treatment of Glioblastoma, by Age and Performance Status

Age, y	KPS Score, %	Treatment Options	Category
≤70	≥60	<ul style="list-style-type: none"> <li>• Standard RT plus concurrent and adjuvant temozolomide plus TTF</li> <li>• Standard RT plus concurrent and adjuvant temozolomide</li> </ul>	1
≤70	<60	<ul style="list-style-type: none"> <li>• Hypofractionated RT with/without concurrent or adjuvant temozolomide</li> <li>• Temozolomide</li> <li>• Palliative/best supportive care</li> </ul>	2A

### U.S. PREVENTIVE SERVICES TASK FORCE RECOMMENDATIONS

Not applicable.

### ONGOING AND UNPUBLISHED CLINICAL TRIALS

Some currently unpublished trials that might influence this review are listed in Table 12. Of particular note are the phase 3 trials evaluating TTF therapy in non-small-cell lung cancer and pancreatic cancer. TTF therapy is an active area of research for mechanisms underlying its effects on cancer cells.

**Table 12.** Summary of Key Trials

NCT No.	Trial Name	Planned Enrollment	Completion Date
Ongoing			
NCT01971281 <sup>a</sup>	A Phase II Study of TTFields (150 kHz) Concomitant With Gemcitabine and TTFields Concomitant With Gemcitabine Plus Nab-paclitaxel for Front-line Therapy of Advanced Pancreatic Adenocarcinoma	40	Dec 2017 (ongoing)
NCT01894061 <sup>a</sup>	A Prospective Phase II Trial of NovoTTF-100A With Bevacizumab (Avastin) in Patients With Recurrent Glioblastoma	40	Dec 2018
NCT02663271 <sup>a</sup>	A Phase 2, Multi-center, Single Arm, Histologically Controlled Study Testing the Combination of TTFields and Pulsed	18	Mar 2019

NCT No.	Trial Name	Planned Enrollment	Completion Date
	Bevacizumab Treatment in Patients With Bevacizumab-refractory Recurrent Glioblastoma		
NCT02831959 <sup>a</sup>	Pivotal, Open-label, Randomized Study of Radiosurgery With or Without Tumor Treating Fields (TTFields) (150kHz) for 1-10 Brain Metastases From Non-small Cell Lung Cancer (NSCLC) (METIS)	270	Jul 2019
NCT02973789 <sup>a</sup>	LUNAR: Pivotal, Randomized, Open-label Study of Tumor Treating Fields (TTFields) Concurrent With Standard of Care Therapies for Treatment of Stage 4 Non-small Cell Lung Cancer (NSCLC) Following Platinum Failure	534	Dec 2021
NCT02743078 <sup>a</sup>	Phase II Trial Of Optune® Plus Bevacizumab In Bevacizumab-Refractory Recurrent Glioblastoma	85	Aug 2022
NCT03377491 <sup>a</sup>	EF-27 Pivotal, Randomized, Open-label Study of Tumor Treating Fields (TTFields, 150kHz) Concomitant With Gemcitabine and Nab-paclitaxel for Front-line Treatment of Locally-advanced Pancreatic Adenocarcinoma (PANOV3)	556	Dec 2022

NCT: national clinical trial.

<sup>a</sup> Denotes industry-sponsored or cosponsored trial.

## CODING

**The following codes for treatment and procedures applicable to this policy are included below for informational purposes. Inclusion or exclusion of a procedure, diagnosis or device code(s) does not constitute or imply member coverage or provider reimbursement. Please refer to the member's contract benefits in effect at the time of service to determine coverage or non-coverage of these services as it applies to an individual member.**

### CPT/HCPCS

### Title: Tumor-Treatment Fields Therapy for Glioblastoma

#### Description/Background

Glioblastoma multiforme is the most common and deadly malignant brain tumor. It has a very poor prognosis and is associated with low quality of life during the course of treatment. Tumor-treatment fields (TTF) therapy is a new, noninvasive technology that is intended to treat glioblastoma using electrical fields.

The Optune device has been approved by the FDA to treat patients with newly-diagnosed glioblastoma multiforme (GBM), an aggressive form of brain cancer. It is given along with the chemotherapy drug temozolomide (TMZ) following standard treatments that include surgery, and a combination of radiation therapy and chemotherapy when used together.

The FDA based its approval of the expanded indication of the Optune device on results from a clinical trial involving 695 patients newly diagnosed with GBM that compared those who used Optune with TMZ to those receiving TMZ alone. Patients who used the device along with TMZ lived, on average, about seven months with no disease progression and survived for an average of 19.4 months after starting treatment. Those who were only treated with TMZ, lived, on average four months with no disease progression and survived for an average of 16.6 months after starting treatment.

In the clinical study used to support the expanded indication, patients treated with the device and TMZ lived on average three months longer than those treated with the drug alone.

#### BACKGROUND

##### Glioblastoma Multiforme

Glioblastomas, also known as glioblastoma multiforme (GBM), are the most common form of malignant primary brain tumor in adults, and they comprise approximately 15% of all brain and central nervous system tumors and more than 50% of all tumors that arise from glial cells.(1)

The peak incidence for GBM occurs between the ages of 45 and 70 years. GBMs are grade IV astrocytomas, the most deadly type of glial cell tumor, and are often resistant to standard chemotherapy.(1) According to the National Comprehensive Cancer Network, GBM is the "most lethal brain tumor with only a third of patients surviving for 1 year and less than 5% living beyond 5 years."(2)

### **Treatment of Glioblastoma Multiforme**

The primary treatment for patients newly diagnosed with GBM is to resect the tumor, confirm a diagnosis while debulking the tumor to relieve symptoms of increased intracranial pressure or compression. At that time, some patients may undergo implantation of the tumor cavity with a carmustine (BCNU)-impregnated wafer.(2) Depending on the patient's physical condition, adjuvant radiation therapy, chemotherapy (typically temozolomide), or a combination of the two are sometimes given. After adjuvant therapy, some patients may undergo maintenance therapy with temozolomide. Prognostic factors for success of therapy are age, histology, and performance status or physical condition of the patient.

No standard treatment exists for recurrent GBM. In patients with disease that recurs after initial treatment, additional debulking surgery may be used if recurrence is localized. Other treatment options for recurrent disease include various forms of systemic medications such as bevacizumab, bevacizumab plus chemotherapy (eg, irinotecan, BCNU/chloroethylnitrosourea [CCNU], temozolomide), temozolomide, nitrosourea, PCV (procarbazine, CCNU, vincristine), cyclophosphamide, and platinum-based agents.(2) External beam radiotherapy (EBRT) also may be used to treat recurrent GBM.

Fractionated external-beam radiotherapy after surgery is standard adjuvant therapy and may be used to treat recurrent GBM. Response rates in recurrent disease are less than 10%, and progression-free survival rates at 6 months are less than 20%. (2,3)

### ***Tumor Treatment Field Therapy***

TTF therapy is a new, noninvasive technology that is intended to treat GBM on an outpatient basis using electrical fields. (3-5) TTF therapy exposes cancer cells to alternating electric fields of low intensity and intermediate frequency, which are purported to both selectively inhibit tumor growth and reduce tumor angiogenesis. TTF are proposed to inhibit rapidly dividing tumor cells by two mechanisms; arrest of cell proliferation and destruction of cells while undergoing division. (4,5)

Optune, formerly NovoTTF-100A™ System, is the only legally marketed TTF delivery system available in the United States. Optune is a portable device that generates alternating electrical fields within the body (called tumor treatment fields). The fields are conducted via disposable electrode patches that are attached to the patient's shaved scalp, over the site of the tumor. (3,4) The device is used by the patient at home on a continuous basis (20-24 hours per day) for the duration of treatment, which can last for several months. Patients can carry the device in a backpack or shoulder pack while carrying out activities of daily living. (6)

---

## **Regulatory Status**

The NovoTTF-100A™ System (assigned the generic name of TTF) was approved by FDA in April 2011 through the premarket approval process. (7) The FDA-approved label reads as

follows: “The NovoTTF-100A System is intended as a treatment for adult patients (22 years of age or older) with histologically-confirmed GBM, following histologically or radiologically confirmed recurrence in an upper region of the brain (supratentorial) after receiving chemotherapy. The device is intended to be used as a stand-alone treatment, and is intended as an alternative to standard medical therapy for recurrent GBM after surgical and radiation options have been exhausted.”(7)

In September 2014, FDA approved Novocure’s request to change its product name from NovoTTF-110A System to Optune™. (8)

In October 2015, FDA expanded the indication for Optune™ in combination with temozolomide to include newly diagnosed glioblastoma.(6) The device was granted priority review status in May 2015 because there was no legally marketed alternative device currently available for the treatment of newly diagnosed GBM that represents a life-threatening condition.

Optune was initially approved in 2011, by the FDA, to treat patients with GBM that recurred or progressed after chemotherapy. With the 2015 expanded indication, Optune™ can be used as part of a standard treatment for GBM before the disease progresses. For newly diagnosed GBM, Optune™ is not intended to be used as a substitute for standard treatments, but rather as an adjunct therapy.

For newly diagnosed GBM, Optune™ is given along with the chemotherapy drug temozolomide (TMZ) following standard treatments that include surgery and the combination of radiation and chemotherapy. Optune™ should not be used without a physician’s supervision. Patients should not use Optune™ if they have an active implanted medical device, a skull defect or known sensitivity to conductive hydrogels, such as those used on electrocardiogram stickers. (21)

---

## Medical Policy Statement

The safety and effectiveness of tumor-treatment fields (TTF) therapy has been established. It is a useful therapeutic option for patients meeting specific selection criteria.

---

## Inclusionary and Exclusionary Guidelines (Clinically based guidelines that may support individual consideration and pre-authorization decisions)

### Inclusions:

Tumor treatment field therapy may be medically necessary when prescribed by a physician for the treatment of newly diagnosed, histologically confirmed supratentorial glioblastoma multiforme in:

- Adults (22 years of age and older) **AND**
- When used as an adjunct therapy to standard treatments that include maximal debulking surgery and completion of radiation together with the chemotherapy drug temozolomide (TMZ)

**OR**

- For adults 22 years of age and older with reoccurrence of histologically or radiologically confirmed supratentorial glioblastoma multiforme, the Tumor Treatment Fields may be used as monotherapy as an alternative to standard medical therapy

### **Exclusions:**

Tumor treatment field therapy is considered investigational/experimental:

- Combined with chemotherapy other than TMZ
- When used for any indications other than those listed above

---

**CPT/HCPCS Level II Codes** *(Note: The inclusion of a code in this list is not a guarantee of coverage. Please refer to the medical policy statement to determine the status of a given procedure.)*

### **Established codes:**

A4555	E0766	95999
-------	-------	-------

### **Other codes (investigational, not medically necessary, etc.):**

E1399	A9900	77299
-------	-------	-------

---

## **Rationale**

Re-radiation options are limited for glioblastoma (GBM) patients who have received initial external-beam radiotherapy due to radiation tolerances. The tumors are locally invasive but do not metastasize, therefore, tumor treating fields (TTF) therapy as a locoregional intervention is proposed to treat GBM. For this review, 2 indications will be considered: (1) TTF as an alternative to chemotherapy in progressive or recurrent GBM and (2) TTF as an adjunct to maintenance treatment in patients following initial treatment. Comparative trials are essential to determine efficacy in this area, and randomized controlled trials (RCTs) are needed to control for heterogeneity in the patient populations and other confounders of outcome. This review will include both RCTs and nonrandomized comparative trials.

## **TTF AS AN ALTERNATIVE TO CHEMOTHERAPY FOR PROGRESSIVE OR RECURRENT GBM**

### **Randomized Controlled Trials**

The U.S. Food and Drug Administration (FDA) approval of the NovoTTF-100A system was based on a phase 3, multinational prospective randomized controlled trial (RCT) (EF11) which was published in 2012 by Stupp et al. The Stupp study, which was sponsored and funded by the manufacturer of the device (Novocure), compared TTF therapy (delivered by the NovoTTF-100A System) with the best standard of care chemotherapy (active control). Twenty-eight clinical centers (across 7 countries) enrolled 237 adult participants with relapsed or progressive glioblastoma multiforme (GBM), despite conventional radiotherapy. Other prior treatments may have included surgery and/or chemotherapy. Patient characteristics were balanced in both groups, with median age of 54 years and median Karnofsky Performance Status score of 80%. More than 80% of participants had failed 2 or more prior chemotherapy regimens ( $\geq$  second recurrence), and 20% had failed bevacizumab prior to study enrollment.

Two hundred thirty-seven patients were randomized in a 1:1 ratio to receive TTF therapy only (n=120) or active control (n=117). The choice of chemotherapy regimens varied, reflecting local practice at each of the participating clinical centers. Chemotherapy agents considered as active control during the trial included platinum-based chemotherapy (ie, carboplatin); nitrosureas; procarbazine; combination of procarbazine, lomustine and vincristine (PCV); temozolomide; and bevacizumab. For patients assigned to the TTF group, uninterrupted treatment was recommended, although patients were allowed to take treatment breaks of up to 1 hour, twice per day, for personal needs (eg, shower). In addition, patients assigned to the TTF group were allowed to take 2 to 3 days off treatment at the end of each of 4-week period (which is the minimal required treatment duration for TTF therapy to reverse tumor growth). A period of 28 days of treatment with TTF was considered 1 full treatment course.

The study was designed as a superiority trial. The primary study end point in this RCT was overall survival (OS).(3) Secondary end points included progression-free survival (PFS) at 6 months, time to progression, 1-year survival rate, quality of life (QOL), and radiological response. All end points were evaluated using intention-to-treat analysis. Participants were seen in clinic monthly, and magnetic resonance imaging (MRI) was performed after 2, 4, and 6 months from initiation of treatment, with subsequent MRIs done according to local practice until disease progression. Medical follow-up continued for 2 months after disease progression. Monthly telephone interviews with the participants' caregivers were used to assess mortality rates.

Ninety-seven percent (116) of 120 participants in the TTF group started treatment and 93 participants (78%) completed 1 cycle (4 weeks) of therapy. Discontinuation of TTF therapy occurred in 27 participants (22%) due to noncompliance or the inability to handle the device.(3) For each TTF treatment month, the median compliance was 86% (range, 41%-98%), which equaled a mean use of 20.6 hours per day. In the active control group, 113 (97%) of the 117 assigned participants received chemotherapy and all except 1 individual completed a full treatment course. Twenty-one participants (18%) in the active control group did not return to the treating site and details on disease progression and toxicity were not available.

We summarize study outcomes in Table 1.

**Table 1. Randomized Trial of TTF Versus Physicians' Choice Chemotherapy in Recurrent Glioblastoma: Principal Efficacy Results From Stupp et al**

Outcomes	TTF	Chemotherapy	Measure of Association, Significance
Median survival, mo	6.6	6.0	
Hazard ratio survival			0.86 (95% CI, 0.66 to 1.12) favors TTF
Radiologic response (not all patients evaluated)	14%	9.6%	p=0.19
Median PFS, mo	2.2	2.1	
Hazard ratio PFS			0.81 (95% CI, 0.60 to 1.09) favors TTF

CI: confidence interval; PFS: progression-free survival; TTF: tumor treatment fields.

The trial did not reach its primary end point of improved survival compared to active chemotherapy. With a median follow-up of 39 months, 220 participants (93%) had died. Median survival was 6.6 months in the TTF group compared to 6.0 months in the active control group (hazard ratio, 0.86; 95% confidence interval [CI], 0.66 to 1.12; p=0.27). For both groups, 1-year survival was 20%. The survival rates for 2- and 3-year survival were 8% and 4%, respectively, for the TTF group versus 5% and 1%, respectively, for the active control group. PFS rate at 6 months was 21.4% in the TTF group, compared to 15.1% in the active control

group ( $p=0.13$ ). Objective radiological responses (partial and complete response) were noted in 14 participants in the TTF group and 7 in the active control group, with a calculated response rate of 14.0% (95% CI, 7.9% to 22.4%) compared to 9.6% (95% CI, 3.9% to 18.8%), respectively. Sixteen percent of the TTF participants had grade 1 and 2 contact dermatitis on the scalp, which resolved with topical corticosteroids. Active control participants experienced grade 2-4 events by organ system related to the pharmacologic activity of chemotherapy agents utilized; severe (grades 3 and 4) toxicity was observed in 3% of participants.

Longitudinal QOL data were available in 63 participants (27%). There were no meaningful differences observed between the groups in the domains of global health and social functioning. However, cognitive, emotional, and role functioning favored TTF therapy; physical functioning favored chemotherapy. Symptom scale analysis was in accordance to treatment-associated toxicity; appetite loss, diarrhea, constipation, nausea, and vomiting were directly related to the chemotherapy administration. Increased pain and fatigue was reported in the chemotherapy-treated patients and not in the TTF group.

Wong et al published a subgroup analysis of the Stupp RCT (previously described) to determine characteristics of responders and nonresponders in the treatment and active control groups.(9) Tumor response was assessed by the Macdonald criteria. More patients in the TTF arm were considered responders (14/120 vs 7/117 in the chemotherapy arm.) Median response time was longer for those in the TTF arm than the chemotherapy arm (7.3 months vs 5.6 months,  $p<0.001$ ), and there was a strong correlation (Pearson's  $r$ ) between response and OS in the TTF arm ( $p<0.001$ ) but not in chemotherapy arm ( $p=0.29$ ). Compared with the chemotherapy arm, a higher proportion of responders in the TTF arm had a prior low-grade histology (36% vs 0%). These differences in treatment responder groups suggest that TTF therapy may differentially benefit certain types of GBM; however, the small numbers of responders in both groups limits generalizations that can be drawn from this analysis.

A second post hoc analysis of the TTF EF-11 pivotal trial data was performed to evaluate OS rates among patients who completed at least 1 complete course of TTF or chemotherapy. (10) Investigators analyzed survival in what they referred to as a "modified ITT [intention-to-treat]" subgroup comprising 93 of 120 (78%) of the original TTF allocated group, versus 117 of 117 (100%) of the original chemotherapy allocated group. This exercise revealed median OS of 7.7 months in the TTF modified ITT (mITT) group compared with 5.9 months in the chemotherapy group (HR=0.69; 95% CI, 0.52 to 0.91;  $p=0.009$ ). They also showed a trend relationship between proportion of patients with higher TTF compliance and median OS rates ( $p=0.039$ ). The investigators suggest that TTF provides an OS benefit if used as intended in the FDA-approved label when compared with best chemotherapy. This post hoc analysis is limited as it was not prespecified in the study, includes only 78% of the original TTF allocated patients, and fails to control for noncompliance due to faster clinical deterioration of TTF recipients leading to treatment cessation.

### **Noncomparative Studies**

Two nonrandomized studies were identified that compared TTF treatment with standard care using historical controls. A study published in late 2014 included OS data from 457 patients included in the Patient Registry Dataset (PRiDe), a postmarketing registry of all recurrent GBM patients who received NovoTTF therapy in a real-world, clinical practice setting in 91 centers in the United States between October 2011 and November 2013.(11) The median OS rate in the PRiDe clinical practice dataset was reported as significantly superior to that attained in the TTF

EF-11 pivotal trial (9.6 months vs 6.6 months; HR=0.66, 95% CI, 0.05 to 0.86;  $p<0.001$ ). One- and 2-year OS rates for TTF in PRiDe were significantly longer than those in the TTF group in the EF-11 trial (44% vs 20% at 1 year; 30% vs 9% at 2 years, respectively). The PRiDe investigators reported no novel or unexpected treatment-related adverse events compared with the EF-11 trial.

Kirson et al (2007) reported the findings of a study examining the effects of TTF therapy delivered by the NovoTTF-100A System in 10 patients with recurrent glioblastoma multiforme (GBM).(12) Median time to progression (TTP) in these patients was 26.1 weeks and median overall survival (OS) was 62.2 weeks. The authors noted that these TTP and OS values were more than double the reported medians of historical control patients. No device-related serious adverse events were seen after more than 70 months of cumulative treatment in all of the patients. The only device-related adverse event observed was a mild-to-moderate contact dermatitis beneath the field delivering electrodes. The primary limitation of this study was the use of historical controls, since the patients included may not be comparable on major clinical and prognostic features.

Two small case series have been published of long-term survival (>6 years) with TTF therapy.(14,15) Rulseh et al reported long-term (>7 year) survival in 4 of 20 patients with GBM who were treated with TTF,(14) while Villano et al describe 1 patient with recurrent GBM who was tumor-free more than 6 years after treatment with TTF.(15)

### **Section Summary: TTF Therapy as an Alternative to Chemotherapy for Progressive or Recurrent GBM**

Multiple case reports and small case series have concluded that TTF treatments are similar to outcomes following standard chemotherapy, with a decrease in toxicity and increase in quality of life favoring TTF.(16) Although global health and social functioning didn't show meaningful differences, cognitive, emotional and role functioning favored TTF therapy. Increased pain and fatigue was reported in the chemotherapy-treated patients and not in the TTF group.

Treatment-associated toxicity such as appetite loss, diarrhea, constipation, nausea and vomiting were directly related to the chemotherapy administration, but not reported with the TTF. The most common side effect reported during TTF treatment was a mild-to-moderate contact dermatitis beneath the field delivering electrodes. Overall, TTF yielded a longer OS in recurrent and advance GBM when compared to chemotherapy. TTF appears to provide an OS benefit when used as intended per the FDA approval.

### **TTF THERAPY AS AN ADJUNCT TO STANDARD MAINTENANCE CARE FOR GBM**

In 2015, Stupp et al published a planned interim analysis of a multicenter, open-label RCT that evaluated maintenance therapy with TTF for GBM. (13) This trial enrolled patients with GBM who had completed standard treatment consisting of biopsy or surgical resection followed by chemoradiotherapy with temozolomide. A Karnofsky Performance Status score of 70% or higher was an additional inclusion criterion. Patients were randomized in a 2:1 fashion to TTF plus temozolomide or to temozolomide alone. At the time of the interim analysis, 210 patients were randomized to TTF plus temozolomide and 105 patients to temozolomide alone. The primary outcome was PFS analyzed by intention-to-treat; a secondary outcome was OS analyzed by per-protocol analysis.

Patients in the TTF group received continuous TTF therapy delivered mainly in the home setting. Patients were trained on use of the device, including changing the electrodes, and then

treatment continued at home. Patients were encouraged to wear the device continuously, with the exception of short breaks to attend to personal needs. All patients were seen monthly for follow-up. Further, MRI was performed every 2 months and QOL measures administered every 3 months. Tumor progression was adjudicated by a central review committee blinded to treatment group.

Planned interim analysis was performed at a median follow-up of 38 months (range, 18-60 months). Median PFS and median OS are summarized in Table 2.

**Table 2. TTF Therapy as an Adjunct to Standard Maintenance Care in Glioblastoma Multiforme**

Group	N	Progression-Free Survival (95% CI), mo	Hazard Ratio (98.7% CI)	Overall Survival (95% CI), mo	Hazard Ratio (99.4% CI)
TTF + temozolomide	210 (196 <sup>a</sup> )	7.1 (5.9 to 8.2)	0.62 (0.43 to 0.89)	20.5 (16.7 to 25)	0.64 (0.42 to 0.98)
Temozolomide alone	105 (84 <sup>a</sup> )	4.0 mo (3.3 to 5.2)		15.6 mo (13.3 to 19.1)	

CI: confidence interval; TTF: tumor treatment fields.

<sup>a</sup> Included in per-protocol analysis.

There were 35 (11%) dropouts during the trial - 14 (6.7%) of 210 patients in the TTF group and 21 (20%) of 105 in the temozolomide-alone group. Adherence to treatment was defined as wearing the device for at least 18 hours a day, and 157 (75%) of 210 patients met this adherence criterion. The number of treatment cycles with temozolomide differed between groups. The TTF group received a median of 6 cycles compared with a median of 4 cycles for the temozolomide-alone group. The most common side effect of treatment was local skin irritation, which occurred in 43% of patients treated with TTF.

In October 2014, the trial independent data and safety monitoring committee reviewed the interim analysis, concluding that the trial met its predefined boundaries for success (improvement in PFS and OS) and recommended trial termination. The FDA approved study termination and the trial was closed to recruitment that November after 695 of the planned 700 participants had been randomized. All patients in the control maintenance therapy arm could crossover to receive TTFs. At the time of the Stupp interim analysis, 35 control arm participants had crossed over. FDA considered the results of this analysis for the 2015 expanded approval of Optune.

### **Section Summary: TTF Therapy as an Adjunct to Standard Maintenance Care for GBM**

The single RCT for this indication reports that PFS is improved by 3.1 months and OS is improved by 4.9 months after the addition of TTF to standard maintenance therapy (ie, temozolomide). Therefore, there may be a survival benefit associated with TTF for this indication.

### **SUMMARY OF EVIDENCE**

The evidence for tumor-treatment field therapy in patients who have recurrent or progressive glioblastoma multiforme includes 1 randomized controlled superiority pivotal trial using the U.S. Food and Drug Administration– approved device and a number of small observational studies. Relevant outcomes include overall survival (OS), quality of life (QOL), and treatment-related morbidity. GBM is the most common brain tumor, has a low quality of life during the course of treatment and has a poor prognosis. TTF therapy offers a noninvasive approach to newly diagnosed and recurrent tumors. In 2011 the FDA approved TTF therapy for use in recurrent

tumors. In 2015 the FDA expanded its recommendations for use in newly diagnosed GBM which meet specified criteria.

Studies indicated that patients treated with the device and TMZ had a longer progression-free survival of 3.1 months and an overall survival of 4.9 months longer than those who were treated with only TMZ. For individuals who have advanced or recurrent GBM and receive TTF as an alternative to standard chemotherapy, no difference was noted in overall survival.

Furthermore, there is consensus within the National Comprehensive Cancer Network that indicates consideration of alternating electric field therapy in the treatment of a recurrent glioblastoma brain tumor is appropriate.

The use of TTF therapy has been described in a number of case series. High quality studies are difficult to obtain related to the mortality rate associated with GBM. Published studies indicate that some patients who underwent TTF therapy achieved long-term survival of > 5-7 years. TTF therapy appeared to offer a higher survival rate than chemotherapy alone with the only side effect being contact dermatitis of the scalp; thus, offering a better outcome through increased quality and quantity of life.

## ONGOING AND UNPUBLISHED CLINICAL TRIALS

Some currently unpublished trials that might influence this review are listed in Table 3.

**Table 3. Summary of Key Trials**

NCT No.	Trial Name	Planned Enrollment	Completion Date
<b>Ongoing</b>			
NCT01894061 <sup>a</sup>	A Prospective Phase II Trial of NovoTTF-100A With Bevacizumab (Avastin) in Patients With Recurrent Glioblastoma	40	Dec 2017
NCT01756729 <sup>a</sup>	A Prospective, Non-randomized, Concurrent Control, Open Label, Post-approval Study of NovoTTF-100A in Recurrent GBM Patient	486	Jan 2018
NCT02743078 <sup>a</sup>	Phase II Trial Of Optune® Plus Bevacizumab In Bevacizumab-Refractory Recurrent Glioblastoma	85	Apr 2018
NCT01954576	A Phase II Study of the NovoTTF-100A system, Enhanced by Genomic Analysis to Identify the Genetic Signature of Response in the Treatment of Recurrent Glioblastoma Multiforme	30	May 2018
NCT02663271 <sup>a</sup>	A Phase 2, Multi-center, Single Arm, Histologically Controlled Study Testing the Combination of TTFields and Pulsed Bevacizumab Treatment in Patients With Bevacizumab-refractory Recurrent Glioblastoma	25	May 2018
NCT02893137 <sup>a</sup>	Phase 1 Enhancing Optune Therapy of Recurrent Glioblastoma Multiforme Using Targeted Surgical Skull Remodeling	15	Oct 2019
NCT01925573 <sup>a</sup>	Proposed Pilot Study of Combined Optune+ Bevacizumab, and Hypofractionated Stereotactic Irradiation for Bevacizumab-Naive Recurrent Glioblastoma	27	Dec 2021

NCT: national clinical trial.

<sup>a</sup> Denotes industry-sponsored or cosponsored trial.

## Supplemental Information

### CLINICAL INPUT RECEIVED FROM PHYSICIAN SPECIALTY SOCIETIES AND ACADEMIC MEDICAL CENTERS

While the various physician specialty societies and academic medical centers may collaborate with and make recommendations during this process, through the provision of appropriate reviewers, input received does not represent an endorsement or position statement by the physician specialty societies or academic medical centers, unless otherwise noted.

In response to requests for input on the use of TTF for treatment of GBM in 2016, BCBSA received input from 1 academic medical center and 3 physician specialty societies, with a total of 9 individual responses. There was majority support, but not consensus, for use of TTF as an adjunct to maintenance treatment following initial therapy for GBM. There was mixed support for use of TTF as an alternative to chemotherapy in advanced or recurrent GBM.

### PRACTICE GUIDELINES AND POSITION STATEMENTS

National Comprehensive Cancer Network guidelines on central nervous system cancers (v.1.2016) (2) include a recommendation for the treatment of glioblastoma. For the initial treatment of patients with glioblastoma with good performance status and either methylated or unmethylated or indeterminate MGMT promotor status, treatment with standard brain radiotherapy plus concurrent temozolomide and adjuvant temozolomide plus alternating electric currents therapy is a category 2A recommendation. Alternating electric currents therapy is only an option for patients with supratentorial disease. Consideration of alternating electric field therapy for recurrent glioblastoma is a 2B recommendation.

### U.S. PREVENTIVE SERVICES TASK FORCE RECOMMENDATIONS

Not applicable.

## Government Regulations

### National:

There is no national coverage determination for TTF.

### Local:

Tumor Treatment Field Therapy

**L34823**; Effective: October 2015, Revised 1/1/17

Tumor treatment field therapy (E0766) will be denied as not reasonable and necessary.

**A52711** Effective date: 10/01/15, Revised 1/1/17

### NON-MEDICAL NECESSITY COVERAGE AND PAYMENT RULES:

For any item to be covered by Medicare, it must 1) be eligible for a defined Medicare benefit category, 2) be reasonable and necessary for the diagnosis or treatment of illness or injury or to improve the functioning of a malformed body member, and 3) meet all other applicable Medicare statutory and regulatory requirements.

Information provided in this policy article relates to determinations other than those based on

Social Security Act §1862(a)(1)(A) provisions (i.e. “reasonable and necessary”). TUMOR TREATMENT FIELD therapy devices are covered under the Durable Medical Equipment benefit (Social Security Act §1861(s)[6]). In order for a beneficiary’s equipment to be eligible for reimbursement the reasonable and necessary (R&N) requirements set out in the related Local Coverage Determination must be met. In addition, there are specific statutory payment policy requirements, discussed below, that also must be met.

Code E0766 is in the frequent and substantial service payment category. Items included in this payment category are reimbursed a single monthly fee schedule amount for the device and all related supplies and accessories. Separate billing of supplies and/or accessories will be denied as unbundling.

Code A4555 is not valid for billing to Medicare. If code A4555 is billed, it will be denied as an invalid code.

### **Michigan Department of Health & Human Services:**

Codes E0766 and A4555 are not listed on the MDHHS DME POS fee schedule.

*(The above Medicare information is current as of the review date for this policy. However, the coverage issues and policies maintained by the Centers for Medicare & Medicare Services [CMS, formerly HCFA] are updated and/or revised periodically. Therefore, the most current CMS information may not be contained in this document. For the most current information, the reader should contact an official Medicare source.)*

**BLUE CARE NETWORK BENEFIT COVERAGE**  
**POLICY: TUMOR-TREATMENT FIELDS THERAPY FOR GLIOBLASTOMA**

**I. Coverage Determination:**

<b>Commercial HMO (includes Self-Funded groups unless otherwise specified)</b>	Covered; criteria apply
<b>BCNA (Medicare Advantage)</b>	Refer to the Medicare information under the Government Regulations section of this policy.
<b>BCN65 (Medicare Complementary)</b>	Coinsurance covered if primary Medicare covers the service.

**II. Administrative Guidelines:**

- The member's contract must be active at the time the service is rendered.
- Coverage is based on each member's certificate and is not guaranteed. Please consult the individual member's certificate for details. Additional information regarding coverage or benefits may also be obtained through customer or provider inquiry services at BCN.
- The service must be authorized by the member's PCP except for Self-Referral Option (SRO) members seeking Tier 2 coverage.
- Services must be performed by a BCN-contracted provider, if available, except for Self-Referral Option (SRO) members seeking Tier 2 coverage.
- Payment is based on BCN payment rules, individual certificate and certificate riders.
- Appropriate copayments will apply. Refer to certificate and applicable riders for detailed information.
- CPT - HCPCS codes are used for descriptive purposes only and are not a guarantee of coverage.

Medical Policy:	II-164-003
Topic:	Tumor Treatment Fields Therapy
Section:	Medicine
Effective Date:	March 27, 2017
Issue Date:	March 27, 2017
Last Reviewed:	March 2017

---

Tumor treatment fields (TTF) therapy exposes cancer cells to alternating electric fields of low intensity and intermediate frequency. The use of TTF is proposed to inhibit rapidly dividing tumor cells by arresting cell proliferation, leading to destruction of cells.

Optune™ (formerly known as the NovoTTF-100A™ System) received premarket approval (PMA) from the U.S. Food and Drug Administration (FDA) in 2011 as a treatment for adult patients (22 years of age or older) with confirmed glioblastoma multiforme (GBM), following confirmed recurrence in an upper region of the brain (supratentorial) after receiving chemotherapy. The device is intended to be used as a stand-alone treatment, and is intended as an alternative to standard medical therapy for recurrent GBM after surgical and radiation options have been exhausted. In October 2015, the FDA approved the Optune™ with temozolomide for the treatment of adult patients (22 years of age or older) with newly diagnosed, supratentorial glioblastoma following maximal debulking surgery and completion of radiation therapy together with concomitant standard of care chemotherapy.

Glioblastoma is also known as glioblastoma multiforme (GBM). The term "multiforme" is no longer part of the World Health Organization (WHO) designation, though glioblastoma is still often abbreviated "GBM." Glioblastoma is the most common form of malignant primary brain tumor in adults, and comprises approximately 15% of all brain and central nervous system tumors. Glioblastoma is a WHO grade IV astrocytoma, the most deadly type of glial cell tumor, which is often resistant to standard chemotherapy.

Tumor treatment fields therapy for glioblastoma is delivered by a battery-powered, portable device that generates the electrical fields via disposable electrodes that are noninvasively attached to the patient's shaved scalp over the site of the tumor. The device is used by the patient at home on a continuous basis (20-24 hours per day) for the duration of treatment, which can last for several months. The use of TTF is also under investigation for several other types of malignancies, including cancers of the breast, lung, ovaries and pancreas, as well as melanoma and solid tumor brain metastases.

*This policy is designed to address medical guidelines that are appropriate for the majority of individuals with a particular disease, illness, or condition. Each person's unique clinical circumstances may warrant individual consideration, based on review of applicable medical records.*

**Policy Position:** Coverage is subject to the specific terms of the member's benefit plan.

**I. Tumor treatment fields (TTF) therapy may be considered **MEDICALLY NECESSARY** for patients who meet **ALL** of the following criteria:**

- History of histologically confirmed glioblastoma (World Health Organization grade IV astrocytoma); **AND**
- Recurrence of glioblastoma in the supratentorial region of the brain has been histologically or radiologically confirmed; **AND**
- After surgery, radiation and chemotherapy, or patient is not a candidate for these treatments.

**II. Tumor treatment fields (TTF) therapy is considered **INVESTIGATIVE** for all other indications including, but not limited to treatment of other malignancies (e.g., cancers of the breast, lung, ovaries, pancreas, melanoma and solid tumor brain metastases). There is a lack of evidence demonstrating an impact on improved health outcomes for treatment of conditions other than recurrent glioblastoma.**

### Tumor-Treatment Fields Therapy

**File Name:** tumor\_treatment\_fields\_therapy  
**Origination:** 9/2013  
**Last CAP Review:** 11/2017  
**Next CAP Review:** 11/2018  
**Last Review:** 6/2018

#### Description of Procedure or Service

---

Tumor-treatment fields therapy is a noninvasive technology that uses alternating electrical fields. It is used to treat glioblastoma multiforme, and has been proposed for use in other tumor types.

##### **Background**

Glioblastoma, also known as glioblastoma multiforme (GBM), is the most common form of malignant primary brain tumor in adults, comprising approximately 15% of all brain and central nervous system tumors and more than 50% of all tumors that arise from glial cells. The peak incidence for GBM occurs between the ages of 45 and 70 years. GBMs are grade IV astrocytomas, a rapidly progressing and deadly type of glial cell tumor, which is often resistant to standard chemotherapy. According to the National Comprehensive Cancer Network (NCCN), GBM is the "deadliest brain tumor with only a third of patients surviving for one year and less than 5% living beyond 5 years."

The primary treatment for newly diagnosed GBM is debulking surgery to remove as much of the tumor as possible. At the time of surgery, some patients may undergo implantation of the tumor cavity with a carmustine (BCNU) -impregnated wafer. Depending on the patient's physical condition, adjuvant radiation therapy, chemotherapy (typically temozolomide), or a combination of the two is recommended. After adjuvant therapy, some patients may undergo maintenance therapy with temozolomide. Maintenance temozolomide is given for 5 days of every 28-day cycle for 6 cycles.

No standard treatment exists for recurrent GBM. In patients with disease that recurs after these initial therapies, additional debulking surgery may be used if recurrence is localized. Other treatment options for recurrent disease include various forms of systemic medications such as bevacizumab, bevacizumab plus chemotherapy (e.g., irinotecan, BCNU/CCNU, temozolomide), temozolomide, nitrosourea, PCV (procarbazine, CCNU, and vincristine), cyclophosphamide, and platinum-based agents. External beam radiotherapy also may be used to treat recurrent GBM. Response rates in recurrent disease are less than 10%, and progression-free survival rates at 6 months are less than 20%.

Tumor-treatment fields (TTF) therapy is a noninvasive technology that is intended to treat GBM on an outpatient basis using electrical fields. TTF therapy exposes cancer cells to alternating electric fields of low intensity and intermediate frequency, which are purported to both selectively inhibit tumor growth and reduce tumor angiogenesis. Tumor-treatment fields are proposed to inhibit rapidly dividing tumor cells by two mechanisms, arrest of cell proliferation and destruction of cells while undergoing division.

The NovoTTF-100A™ System (Novocure Ltd., Haifa, Israel) has been approved by the U.S. Food and Drug Administration (FDA) to deliver TTF therapy. TTF therapy via the NovoTTF-

# Tumor-Treatment Fields Therapy

100A™ System is delivered by a battery-powered, portable device that generates the fields via disposable electrodes that are noninvasively attached to the patient's shaved scalp over the site of the tumor. The device is used by the patient at home on a continuous basis (20–24 hours per day) for the duration of treatment, which can last for several months. Patients can carry the device in a backpack or shoulder pack while carrying out activities of daily living.

## **Regulatory Status**

The NovoTTF-100A™ System (assigned the generic name of tumor-treatment fields) was approved by the FDA in April 2011 through the premarket approval process. The FDA-approved indication for use is: "The NovoTTF-100A System is intended as a treatment for adult patients (22 years of age or older) with confirmed GBM, following confirmed recurrence in an upper region of the brain (supratentorial) after receiving chemotherapy. The device is intended to be used as a stand-alone treatment, and is intended as an alternative to standard medical therapy for recurrent GBM after surgical and radiation options have been exhausted."

In September 2014, FDA approved a request for Novocure to change its products name from Novo-TTF-110A System to Optune™.

In October 2015, FDA expanded the indication for Novocure's use of Optune in combination with temozolomide for newly diagnosed glioblastoma.

## **Related Policies**

**\*\*\*Note: This Medical Policy is complex and technical. For questions concerning the technical language and/or specific clinical indications for its use, please consult your physician.**

## **Policy**

---

**BCBSNC will provide coverage for tumor treatment fields therapy when it is determined to be medically necessary because the medical criteria shown below are met.**

## **Benefits Application**

---

This medical policy relates only to the services or supplies described herein. Please refer to the Member's Benefit Booklet for availability of benefits. Member's benefits may vary according to benefit design; therefore member benefit language should be reviewed before applying the terms of this medical policy.

## **When Tumor-Treatment Fields Therapy is covered**

---

Tumor treatment fields (TTF) therapy is considered to be **medically necessary** for the treatment of newly diagnosed, supratentorial glioblastoma multiforme, as an adjunct to standard maintenance therapy with temozolomide when **ALL** of the following conditions are met:

- The patient has completed initial treatment with surgery, radiation therapy and concomitant chemotherapy; **AND**
- The patient is  $\geq 18$  years of age; **AND**
- Has a Karnofsky Performance Status score  $\geq 70\%$ ; **AND**
- There is documentation of lack of tumor progression following radiation and chemotherapy (see Policy Guidelines); **AND**
- The individual is willing and capable of wearing the device for at least 18 hours a day.

# Tumor-Treatment Fields Therapy

## When Tumor-Treatment Fields Therapy is not covered

---

Tumor treatment fields therapy (TTF) is considered investigational, including, but not limited to, the following situations:

- As an alternative or an adjunct to standard medical therapy (eg bevacizumab, chemotherapy) for patients with progressive or recurrent glioblastoma multiforme.
- In the treatment of other types of malignant tumors, including but not limited to, pancreatic adenocarcinoma, lung cancer and brain metastases.

## Policy Guidelines

---

In the EF-14 trial, tumor progression following radiochemotherapy was defined as 25% or more increase in enhancing lesions or any new lesions, as determined by imaging.

For individuals who have newly diagnosed GBM on maintenance therapy after initial treatment with surgery, radiotherapy, and/or chemotherapy who receive TTF therapy as an adjunct to standard maintenance therapy, the evidence includes an RCT. Relevant outcomes include overall survival, disease-specific survival, symptoms, functional outcomes, quality of life, and treatment-related morbidity. The EF-14 trial found a significant increase of 2.7 months in progression-free survival and an increase of 4.9 months in overall survival with the addition of TTF therapy to standard maintenance therapy (ie, temozolomide) in patients with newly diagnosed GBM. Although patients were not blinded to treatment assignment, progression-free survival was assessed by blinded evaluators, and the placebo effects on the objective measure of overall survival are expected to be minimal. This technology represents a clinically significant option in the treatment of patients with GBM, for whom options are limited. The evidence is sufficient to determine that the technology results in a meaningful improvement in the net health outcome.

For individuals who have progressive or recurrent GBM who receive TTF therapy as an adjunct or alternative to standard medical therapy, the evidence includes an RCT and nonrandomized comparative studies. Relevant outcomes are overall survival, disease-specific survival, quality of life, and treatment-related morbidity. The single RCT evaluating TTF therapy for recurrent GBM did not show superiority of TTF therapy for the primary outcome (overall survival) compared with physicians' choice chemotherapy. Because no serious adverse effects have been identified with TTF therapy, this raises the possibility that treatment with TTF might reduce the toxicity associated with treatment for recurrent GBM. A reduction in chemotherapy-associated toxicity without loss of efficacy would be considered a net health benefit. However, this RCT is not sufficient to permit conclusions on the efficacy of the device. Because the trial was not designed as a noninferiority trial, no inferences of noninferiority compared with chemotherapy can be made. Also, quality of life assessment was measured in an insufficient number of patients to reach firm conclusions on differences in quality of life between TTF therapy and medical treatment. The highest quality study of TTF combined with medical treatment for recurrent GBM is a post hoc analysis of the EF-14 trial. A high-quality, prospective RCT is needed. The evidence is insufficient to determine the effects of the technology on health outcomes.

## Billing/Coding/Physician Documentation Information

---

This policy may apply to the following codes. Inclusion of a code in this section does not guarantee that it will be reimbursed. For further information on reimbursement guidelines, please see Administrative Policies on the Blue Cross Blue Shield of North Carolina web site at [www.bcbsnc.com](http://www.bcbsnc.com). They are listed in the Category Search on the Medical Policy search page.

*Applicable codes: A4555, E0766*

# Tumor-Treatment Fields Therapy

BCBSNC may request medical records for determination of medical necessity. When medical records are requested, letters of support and/or explanation are often useful, but are not sufficient documentation unless all specific information needed to make a medical necessity determination is included.

## Tumor Treatment Fields (TTF)

**Section:** Durable Medical Equipment

**Effective Date:** November 1, 2018

**Issued Date:** September 26, 2018

Electrical fields, known as “tumor treatment fields” (TTF), are created by low-intensity, alternating intermediate frequency (100-200 kilohertz [kHz]) electric currents delivered to the malignant tumor site by insulated electrodes placed on skin surface of the tumor site. As a result of the unique shape and electrical characteristics of dividing tumor cells, TTF exposure may damage the dividing cells through anti-microtubule mechanisms and could stop tumor growth while sparing normal tissue.

### Policy Position

TTF may be considered medically necessary when **ALL** of the following indications are met:

- When it is used as an alternative to standard medical therapy, as a monotherapy; **and**
- For treatment of adult patients (22 years of age or older); **and**
- With histologically-confirmed glioblastoma multiforme; **and**
- Following histologically- or radiologically-confirmed recurrence in the Supratentorial region of the brain; **and**
- After receiving chemotherapy; **and**
- After surgical and radiation options have been exhausted.

**OR**

TTF may be considered medically necessary when **ALL** of the following indications are met:

- It is used as an adjunct to standard maintenance therapy; **and**
- For treatment for adult patients (22 years of age or older); **and**
- With histologically-confirmed glioblastoma multiforme; **and**
- When it is used with temozolomide; **and**
- With newly diagnosed, supratentorial glioblastoma, **and**
- Following maximal debulking surgery; **and**
- Completion of radiation therapy; **and**
- Together with concomitant standard of care chemotherapy.

TTF is considered experimental/investigational when above criteria are not met or for any other indications, and therefore, not covered because the safety and/or effectiveness of this service cannot be established by the available published peer-reviewed literature.

### Procedure Codes

## A4555, E0766

**Covered Diagnosis Codes for Procedure Codes A4555 and E0766**

C71.0	Malignant neoplasm of cerebrum, except lobes and ventricles
C71.1	Malignant neoplasm of frontal lobe
C71.2	Malignant neoplasm of temporal lobe
C71.3	Malignant neoplasm of parietal lobe
C71.4	Malignant neoplasm of occipital lobe
C71.5	Malignant neoplasm of cerebral ventricle
C71.6	Malignant neoplasm of cerebellum
C71.7	Malignant neoplasm of brain stem
C71.8	Malignant neoplasm of overlapping sites of brain
C71.9	Malignant neoplasm of brain, unspecified

**Place of Service: Inpatient/Outpatient**

Experimental/Investigational (E/I) services are not covered regardless of place of service.

The use of tumor treatment fields is typically an outpatient procedure which is only eligible for coverage as an inpatient procedure in special circumstances, including, but not limited to, the presence of a co-morbid condition that would require monitoring in a more controlled environment such as the inpatient setting.

**Denial Statements**

Services that do not meet the criteria of this policy will be considered experimental/investigational (E/I). A network provider can bill the member for the experimental/investigational service. The provider must give advance written notice informing the member that the service has been deemed E/I. The member must be provided with an estimate of the cost and the member must agree in writing to assume financial responsibility in advance of receiving the service. The signed agreement must be maintained in the provider's records.

**EFFECTIVE DATE:** 10|01|2018  
**POLICY LAST UPDATED:** 08|07|2018

## OVERVIEW

Glioblastoma multiforme (GBM) is the most common and deadly malignant brain tumor. It has a very poor prognosis and is associated with low quality of life during of treatment. Tumor treatment fields (ITF) therapy is a new, noninvasive technology intended to treat glioblastoma using alternating electric fields.

## MEDICAL CRITERIA

### BlueCHiP for Medicare and Commercial Products:

Tumor treating fields therapy to treat glioblastoma multiforme is considered medically necessary as an adjunct to standard maintenance therapy with temozolomide in patients with newly diagnosed glioblastoma multiforme following initial treatment with surgery, radiotherapy, and/or chemotherapy when **all** of the following criteria are met:

- Adult patients  $\geq 18$  years of age
- Supratentorial tumor
- Karnofsky Performance Status score  $\geq 70\%$  \*
- Patient understands device use, including the requirement for a shaved head, and is willing to comply with to the Food and Drug Administration label guideline to use Optune for at least 18 hours a day and should finish at least 4 full weeks of therapy to get the best response to treatment.

**APPROVAL PERIOD:** 6 months. Services beyond the 6 months will need a new review and meet the above criteria.

### \*KARNOFSKY PERFORMANCE STATUS SCALE DEFINITIONS RATING (%) CRITERIA

- 100 Normal no complaints; no evidence of disease.
- 90 Able to carry on normal activity; minor signs or symptoms of disease. Able to carry on normal activity and to work; no special care needed.
- 80 Normal activity with effort; some signs or symptoms of disease.
- 70 Cares for self; unable to carry on normal activity or to do active work.
- 60 Requires occasional assistance, but is able to care for most of his personal needs. Unable to work; able to live at home and care for most personal needs; varying amount of assistance needed.
- 50 Requires considerable assistance and frequent medical care.
- 40 Disabled; requires special care and assistance.
- 30 Severely disabled; hospital admission is indicated although death not imminent.
- 20 Very sick; hospital admission necessary; active supportive treatment necessary.
- 10 Moribund; fatal processes progressing rapidly. Unable to care for self; requires equivalent of institutional or hospital care; disease may be progressing rapidly.
- 0 Dead

## PRIOR AUTHORIZATION

Prior authorization is required for BlueCHiP for Medicare and recommended for Commercial Products

## **POLICY STATEMENT**

### **BlueCHiP for Medicare and Commercial Products:**

Tumor treating fields therapy is medically necessary when the above criteria is met.

### **BlueCHiP for Medicare**

Tumor treating fields therapy is considered not covered in all other conditions, including but not limited to the following situations:

- As an adjunct to standard medical therapy (eg, bevacizumab, chemotherapy) for patients with progressive or recurrent glioblastoma multiforme
- As an alternative to standard medical therapy for patients with progressive or recurrent glioblastoma multiforme
- For brain metastases
- For cancer in areas other than the brain.

### **Commercial Products:**

Tumor treating fields therapy is considered not medically necessary in all other conditions, including but not limited to the following situations:

- As an adjunct to standard medical therapy (eg, bevacizumab, chemotherapy) for patients with progressive or recurrent glioblastoma multiforme
- As an alternative to standard medical therapy for patients with progressive or recurrent glioblastoma multiforme
- For brain metastases
- For cancer in areas other than the brain.

## **COVERAGE**

Benefits vary between groups/contracts. Please refer to the appropriate Benefit Booklet, Evidence of Coverage or Subscriber Agreement for services not medically necessary or not covered

## **BACKGROUND**

Glioblastoma multiforme (GBM) is the most common and deadly malignant brain tumor. It has a very poor prognosis and is associated with low quality of life during of treatment. Tumor treatment fields (TTF) therapy is a new, noninvasive technology intended to treat glioblastoma using alternating electric fields.

For individuals who have newly diagnosed GBM on maintenance therapy after initial treatment who receive TTF therapy as an adjunct to standard maintenance therapy, the evidence includes a randomized controlled trial (RCT). Relevant outcomes include overall survival, disease-specific survival, symptoms, functional outcomes, quality of life, and treatment-related morbidity. The EF-14 trial found a significant increase of 2.7 months in progression-free survival and an increase of 4.9 months in overall survival with the addition of TTF therapy to standard maintenance therapy (ie, temozolomide) in patients with newly diagnosed GBM. Although patients were not blinded to treatment assignment, progression-free survival was assessed by blinded evaluators, and the placebo effects on the objective measure of overall survival are expected to be minimal. This technology represents a clinically significant option in the treatment of patients with GBM, for whom options are limited. The evidence is sufficient to determine that the technology results in a meaningful improvement in the net health outcome.

For individuals who have progressive or recurrent GBM who receive TTF therapy as an adjunct or alternative to standard medical therapy, the evidence includes an RCT and nonrandomized comparative studies. Relevant outcomes are overall survival, disease-specific survival, quality of life, and treatment-related morbidity. The single RCT evaluating TTF therapy for recurrent GBM did not show superiority of TTF therapy for the primary outcome (overall survival) compared with physicians' choice chemotherapy. Because no serious adverse effects have been identified with TTF therapy, this raises the possibility that treatment with TTF might reduce the toxicity associated with treatment for recurrent GBM. A reduction in

chemotherapy-associated toxicity without loss of efficacy would be considered a net health benefit. However, this RCT is not sufficient to permit conclusions on the efficacy of the device. Because the trial was not designed as a noninferiority trial, no inferences of noninferiority compared with chemotherapy can be made. Also, quality of life assessment was measured in an insufficient number of patients to reach firm conclusions on differences in quality of life between TTF therapy and medical treatment. The highest quality study of TTF combined with medical treatment for recurrent GBM is a post hoc analysis of the EF-14 trial. A high-quality, prospective RCT is needed. The evidence is insufficient to determine the effects of the technology on health outcomes.

## **CODING**

### **BlueCHiP for Medicare and Commercial Products**

The following code is medically necessary/covered when criteria is met.

**E0766:** Electrical stimulation device used for cancer treatment, includes all accessories, any type

The following code is covered when the service is approved

**A4555:** Electrode/transducer for use with electrical stimulation device used for cancer treatment, replacement only

CAM 042      Electric Tumor Treatment Field (TTF)

Category:      Radiology      Last Reviewed: July 2013

Department(s): Medical Affairs      Next Review:      July 2014

Original Date: July 2013

## Description:

Electrical fields known as "tumor treatment fields (TTF)" are created by low-intensity, alternating intermediate frequency (100 – 200 kilohertz [kHz]) electric currents delivered to the malignant tumor site by insulated electrodes placed on skin surface of the tumor site. As a result of the unique shape and electrical characteristics of dividing tumor cells, TTF exposure may damage the dividing cells through anti-microtubule mechanisms and could stop tumor growth while sparing normal tissue.

## Policy:

The use of devices to generate electric tumor treatment fields (ETTF) is **MEDICALLY NECESSARY** as monotherapy for persons with histologically confirmed glioblastoma (World Health Organization grade IV astrocytoma), after histologically or radiologically confirmed recurrence in the supratentorial region of the brain after receiving chemotherapy.

The use of devices to generate electric tumor treating fields (TTF) as a treatment for malignant tumors is considered **INVESTIGATIONAL** for all other indications.

## Rationale:

The use of electric fields and the corresponding effects upon living tissue has been studied in the laboratory and clinical settings. Alternating electric fields at very low frequencies (below one kHz) stimulate excitable tissue resulting from membrane depolarization (Kirson 2004, 2007, 2009; Salzberg, 2008). Electric fields in the tens of kHz to megahertz (intermediate-frequency) alternate too fast to stimulate tissue and results in minute heating. Kirson and colleagues (2004) demonstrated targeted inhibitory effects on dividing cells with the application of alternating electric fields of very low-intensity (less than two V/centimeter [cm]) and intermediate-frequency, called TTF.

Utilizing time-lapse microphotography of mouse melanoma cell cultures, unique cellular processes as a result of TTF

exposure were identified. Prolongation of mitosis in TTF-treated cells was statistically significant, and one quarter of the treated cells was destroyed. Cellular destruction was observed only in mitotic cells, and cells at rest (quiescent) remained intact, both functionally and morphologically. Nuclear rotation was also observed in TTF treated cell cultures. Microtubules, in the form of spatially organized mitotic spindles in dividing cells, have very large electric dipole moments that may be disoriented by TTF forces. In the control cell cultures, 95 percent of the mitotic spindles were intact and exhibited normal features in cells undergoing mitosis compared to 50 percent of abnormal cell activity in TTF-treated cultures. The use of TTF was then applied in vivo, to two animal tumor models (adenocarcinoma and malignant melanoma cells). TTF-treated tumors were significantly smaller compared to the control tumor size, and the surrounding normal tissue was spared from injury. The encouraging preclinical data led to studies of electric TTF treatment in humans.

The U.S. Food and Drug Administration (FDA, 2011) approved NovoTTF-100A System (NovoCure Ltd., Haifa, Israel) as a treatment for adults with histologically-confirmed, recurrent glioblastoma multiforme (GBM) in the supratentorial region of the brain, based on data presented to the committee from a phase III, multinational, randomized, controlled pivotal clinical trial. Twenty-eight clinical centers enrolled 237 adult participants with relapsed or progressive GBM despite conventional therapy (e.g., surgery and chemo-radiotherapy followed by chemotherapy). One hundred twenty participants were randomized in a 1:1 ratio to receive NovoTTF treatment and 117 participants were randomized to the BSC group with effective chemotherapies as practiced at each of the participating clinical centers. Chemotherapy agents considered as BSC during the trial included platinum-based chemotherapy (i.e., carboplatin); nitrosureas (BCNU); procarbazine; combination of procarbazine, lomustine and vincristine (PCV); temozolomide; and bevacizumab. A period of twenty-eight-days of treatment with NovoTTF was considered one full treatment course. Participants treated with NovoTTF were allowed to take breaks from treatment up to an hour, twice per day for personal needs such as showers. The primary endpoint of the study was overall survival (OS). Secondary endpoints included progression free survival rates at 6-months (PFS6); time to progression (TTP), 1-year survival rate; quality of life (QOL); and radiological response. Participants were seen in clinic monthly, and magnetic resonance imaging (MRI) was performed after 2, four and six months from initiation of treatment and subsequent MRIs were done according to local practice until disease progression. Medical follow-up continued for two months after disease progression. Monthly telephone interviews with the participants' caregivers were used to assess participant mortality rates.

Of the 237 enrollees, eight participants (4 in each group) did not receive the assigned therapy. Ninety-7 percent (116) of 120 enrollees in the NovoTTF group started treatment and 93 participants (78 percent) completed one cycle (4 weeks) of therapy. Discontinuation of TTF occurred in 27 participants due to noncompliance or the inability to handle the device. For each TTF treatment month, the median compliance was 86 percent (range 41-98 percent), which equaled a mean use of 20.6 hours per day. In the BSC (active control) group, 113 (97 percent) of the 117 assigned participants received chemotherapy and all completed one full treatment course with the exception of one individual. In the BSC cohort, 21 participants did not return to the site and details on disease progression and toxicity were not available. Stupp and colleagues (2012) noted the median survival of 6.6 months in the TTF group was marginally higher than six months in the BSC group (hazard ratio 0.86 [95 percent confidence interval [CI] 0.66 – 1.12];  $p=0.27$ ). For both groups, one-year survival was 20 percent. The survival rates for 2- and 3-years were 8 percent (95 percent CI 4, 13) and 4 percent (95 percent CI 1, 8) versus 5 percent (95 percent CI 3, 10) and 1 percent (95 percent CI 0, 3) for the TTF cohort compared to the BSC cohort, respectively. With a median follow-up of 39 months, 93 percent (220 participants) had died. Objective radiological responses (partial and complete response) were noted in 14 participants in the TTF group and seven in the BSC group, with a calculated response rate of 14.0 percent (95 percent CI 7.9- 22.4 percent) compared to 9.6 percent (95 percent CI 3.9 – 18.8 percent), respectively. Sixteen percent of the TTF participants had grade one and two contact

dermatitis on the scalp, which resolved with topical steroids. BSC participants experienced grade 2-4 events by organ system related to the pharmacologic activity of chemotherapy agents utilized. Quality of life data were available in 63 participants (27 percent). Based on the QLQ C-30 and BN-20 questionnaires (5 out of six general scales and of nine symptom seven scales including nausea, vomiting, diarrhea, constipation and pain, quality of life was consistently higher in NovoTTF than in the control group. There were no meaningful differences observed between the domains of global health and social functioning. The BSC cohort had a larger decrease in the negative effects of seizures than the TTF cohort. The self-reporting of QOL indicators may be influenced by bias for the treatment group (FDA Label, 2011; Stupp, 2012).

In an industry-sponsored study, Kirson and colleagues (2007) reported results of TTF treatment on various tumor cell lines and animal tumor models and noted "optimal frequencies differed between cancer cell types." Additionally, the effects of a total of 280 weeks of TTF treatment on 10 individuals with recurrent GBM were reported in the pilot study. TTF treatment resulted in a median TTP of 26.1 weeks (range three – 124 weeks) and the PFS6 months of 50 percent (23 - 77 percent confidence interval). The median OS is 62.2 weeks (range 20.3 - 124.0 weeks). One individual achieved a CR and is free from tumor ten months after stopping treatment, and one participant achieved and continues to maintain a PR seven months after stopping treatment. The authors concluded TTF treatment is encouraging when compared to historical average PFS6 of  $15.3 \pm 3.8$  percent and average historical TTP of  $9.5 \pm 1.6$  weeks and an average OS  $29.3 \pm$  six weeks. Mild to moderate contact dermatitis was reported in nine out of ten participants.

In 2009, results from a pilot study of TTF alone and TTF in combination with chemotherapy for individuals with diagnosed GBM were reported (Kirson). In this single arm study, the first group included 10 individuals with recurrent GBM after failure of maintenance temozolomide (Kirson, 2007), and 10 individuals with newly diagnosed GBM treated with TTF combined with temozolomide were in the second cohort. All 20 individuals were treated for an average of one year (range 2.5 – 24 months) continuously. The first group was compared to a matched group of 18 concurrent controls who received salvage chemotherapy for relapsed/recurrent GBM. The TTF-chemotherapy group was compared to a matched group of 32 concurrent controls who received temozolomide alone. In addition, OS for both cohorts was compared to matched historical control data. Data for the first group were reported in 2007 (Kirson). For the group of 10 individuals with newly diagnosed GBM, PFS was significantly different ( $P = 0.0002$ , HR 3.32 [95 percent CI 1.9 – 5.9]) between the TTF-chemotherapy group compared to the matched concurrent and historical controls. The difference in OS was also significant ( $P=0.0018$ ). The authors concluded TTF may also be an effective sensitizer when used concurrently with chemotherapeutic agents.

A pilot study (Salzberg, 2008) included six participants with locally advanced or metastatic malignant tumors (3 cases - skin metastasis from primary breast cancer; one case each: GBM, malignant melanoma, mesothelioma). Participants had no concomitant anti-tumor therapy and had no additional standard therapy available. All six participants had a total of 128 full days of TTF treatment with individual exposure of 13 – 46 days. Compliance was greater than 80 percent. Three out of six participants had grade one skin irritation which was reversible with electrode repositioning and application of topical steroid ointments. A partial response in skin metastasis from primary breast cancer was observed in one participant. Tumor growth was arrested in three participants and one participant had progressive disease. The participant with mesothelioma had stabilization of a portion of the tumor while another part of the tumor had progressive disease. The individual with GBM did not respond to four weeks of treatment. The mixed results and minimal toxicities from TTF warranted "further investigation in larger clinical trials."

Although the NovoTTF-100A device has received FDA approval, the pivotal trial did not achieve the primary endpoint of the study, which was improved survival with NovoTTF treatment in comparison to chemotherapy. In

addition, the long-term safety and efficacy as a treatment for recurrent GBM has not been demonstrated. The expedited premarket approval (PMA) includes a requirement for a post-market non-randomized, unblinded, concurrent control study of NovoTTF-100A in individuals with recurrent GBM. The primary question to be addressed by the study (FDA Label, 2011): "Is the overall survival of patients treated with NovoTTF-100A non-inferior to the survival of patients treated with the best standard of care (chemotherapy)?" There are currently ongoing clinical trials investigating the safety and effectiveness of the novel TTF device. In addition, there are ongoing investigations to determine the optimal TTF dosing for specific tumor types; the use of TTF alone and in combination with chemotherapy agents; and its place in therapy. Currently, published articles include animal studies, in vitro studies and small case series.

Treatment recommendations published by the National Comprehensive Cancer Network<sup>®</sup> (NCCN, 2012) and the National Cancer Institute (NCI, 2012) include surgical resection, radiation therapy and/or chemotherapy as treatment options, and do not include TTF treatment for recurrent GBM.

The NovoTTF-100A System was approved by the U.S. Food and Drug Administration in April, 2011. This novel device was approved to treat adults with glioblastoma multiforme (GBM) that recurs or progresses after receiving chemotherapy and radiation therapy. TTF technology is also being studied as a treatment for other solid tumors such as non-small cell lung cancer and melanoma. There are published data from TTF use to treat tumors in pre-clinical trials and from small case series. However, there is a paucity of published evidence from randomized controlled trials comparing the long term safety and efficacy of TTF as a treatment of tumors.

According to the National Cancer Institute, glioblastoma (World Health Organization grade IV) is also known as glioblastoma multiforme (GBM). The peak incidence for GBM occurs between the ages of 45 and 70 years. Glioblastoma is highly invasive and is the most frequently occurring brain tumor accounting for approximately 12 percent to 15 percent of all brain tumors and 50 percent to 60 percent of all astrocytic tumors. Giant cell glioblastoma and gliosarcoma are two histologic variants of glioblastoma multiforme. According to the NCCN (2012) GBM is the "deadliest brain tumor with only a third of patients surviving for one year and less than 5 percent living beyond five years."

## Tumor Treatment Fields for CNS Cancers Corporate Medical Policy

File Name: Tumor Treatment Fields for CNS Cancers  
File Code: UM.SPSVC.22  
Origination: New policy  
Last Review: 06/2018  
Next Review: 06/2019  
Effective Date: 10/01/2018

### Description/Summary

Glioblastoma multiforme (GBM) is the most common and deadly malignant brain tumor. It has a very poor prognosis and is associated with low quality of life during of treatment. Tumor treatment fields (TTF) therapy is a new, noninvasive technology intended to treat glioblastoma using alternating electric fields.

### Policy

#### Coding Information

Click the links below for attachments, coding tables & instructions.

[Attachment 1](#)

#### When a service may be considered medically necessary

Tumor treating fields therapy to treat glioblastoma multiforme, anaplastic oligodendroglioma, anaplastic astrocytoma, and anaplastic gliomas may be considered medically necessary, in the following situations:

- As an alternative to standard chemotherapy for patients with progressive or recurrent glioblastoma multiforme, anaplastic oligodendroglioma, anaplastic astrocytoma, and anaplastic gliomas after initial or repeat treatment with surgery, radiotherapy, and/or chemotherapy when disease is unresectable or resection not recommended.
- As adjuvant treatment to standard therapy in patients with supratentorial disease and glioblastoma multiforme following initial treatment with surgery, radiotherapy, and/or chemotherapy.

#### When a service is considered investigational

Tumor treating fields therapy is considered investigational for ALL other indications.

## Policy Guidelines

There are no specific codes for the initial application of this system or instruction on use. The patient reapplies the transducer arrays at home after the initial instruction.

## Document Precedence

Blue Cross and Blue Shield of Vermont (BCBSVT) Medical Policies are developed to provide clinical guidance and are based on research of current medical literature and review of common medical practices in the treatment and diagnosis of disease. The applicable **group/individual contract and member certificate language, or employer's benefit plan** if an ASO group, determines benefits that are in effect at the time of service. Since medical practices and knowledge are constantly evolving, BCBSVT reserves the right to review and revise its medical policies periodically. To the extent that there may be any conflict between **medical policy and contract/employer benefit plan language, the member's contract/employer benefit plan language** takes precedence.

## Audit Information

BCBSVT reserves the right to conduct audits on any provider and/or facility to ensure compliance with the guidelines stated in the medical policy. If an audit identifies instances of non-compliance with this medical policy, BCBSVT reserves the right to recoup all non-compliant payments.

## Administrative and Contractual Guidance

### Benefit Determination Guidance

Prior approval is required and benefits are subject to all terms, limitations and conditions of the subscriber contract.

Incomplete authorization requests may result in a delay of decision pending submission of missing information. To be considered complete, see policy guidelines above.

An approved referral authorization for members of the New England Health Plan (NEHP) is required. A prior approval for Access Blue New England (ABNE) members is required. NEHP/ABNE members may have different benefits for services listed in this policy. To confirm **benefits, please contact the customer service department at the member's health plan.**

Federal Employee Program (FEP): Members may have different benefits that apply. For further information please contact FEP customer service or refer to the FEP Service Benefit **Plan Brochure. It is important to verify the member's benefits** prior to providing the service to determine if benefits are available or if there is a specific exclusion **in the member's** benefit.

**Coverage varies according to the member's group or individual contract. Not all groups are** required to follow the Vermont legislative mandates. Member Contract language takes precedence over medical policy when there is a conflict.

If the member receives benefits through an Administrative Services Only (ASO) group, benefits **may vary or not apply. To verify benefit information, please refer to the member's** employer benefit plan documents or contact the customer service department. Language in the employer benefit plan documents takes precedence over medical policy when there is a conflict.

### Policy Implementation/Update information

06/2018	New Policy, input received from external network specialty providers.
---------	---

### Eligible providers

Qualified healthcare professionals practicing within the scope of their license(s).

Approved by BCBSVT Medical Director(s )

Date Approved

## Tumor Treating Fields Therapy

(10129)

(Formerly Tumor Treatment Fields Therapy for Glioblastoma)

Medical Benefit		Effective Date: 10/01/18	Next Review Date: 07/19
Preauthorization	Yes	Review Dates: 09/15, 05/16, 09/16, 09/17, 07/18	

### Preauthorization is required.

The following protocol contains medical necessity criteria that apply for this service. The criteria are also applicable to services provided in the local Medicare Advantage operating area for those members, unless separate Medicare Advantage criteria are indicated. If the criteria are not met, reimbursement will be denied and the patient cannot be billed. Please note that payment for covered services is subject to eligibility and the limitations noted in the patient's contract at the time the services are rendered.

### DESCRIPTION

Glioblastoma multiforme (GBM) is the most common and deadly malignant brain tumor. It has a very poor prognosis and is associated with low quality of life during of treatment. Tumor treatment fields (TTF) therapy is a new, noninvasive technology intended to treat glioblastoma using alternating electric fields.

### SUMMARY OF EVIDENCE

For individuals who have newly diagnosed GBM on maintenance therapy after initial treatment who receive TTF therapy as an adjunct to standard maintenance therapy, the evidence includes a randomized controlled trial (RCT). Relevant outcomes include overall survival, disease-specific survival, symptoms, functional outcomes, quality of life, and treatment-related morbidity. The EF-14 trial found a significant increase of 2.7 months in progression-free survival and an increase of 4.9 months in overall survival with the addition of TTF therapy to standard maintenance therapy (i.e., temozolomide) in patients with newly diagnosed GBM. Although patients were not blinded to treatment assignment, progression-free survival was assessed by blinded evaluators, and the placebo effects on the objective measure of overall survival are expected to be minimal. This technology represents a clinically significant option in the treatment of patients with GBM, for whom options are limited.

The evidence is sufficient to determine that the technology results in a meaningful improvement in the net health outcome.

For individuals who have progressive or recurrent GBM who receive TTF therapy as an adjunct or alternative to standard medical therapy, the evidence includes an RCT and nonrandomized comparative studies. Relevant outcomes are overall survival, disease-specific survival, quality of life, and treatment-related morbidity. The single RCT evaluating TTF therapy for recurrent GBM did not show superiority of TTF therapy for the primary outcome (overall survival) compared with physicians' choice chemotherapy. Because no serious adverse effects have been identified with TTF therapy, this raises the possibility that treatment with TTF might reduce the toxicity associated with treatment for recurrent GBM. A reduction in chemotherapy-associated toxicity without loss of efficacy would be considered a net health benefit. However, this RCT is not sufficient to permit conclusions on the efficacy of the device. Because the trial was not designed as a noninferiority trial, no inferences of noninferiority compared with chemotherapy can be made. Also, quality of life assessment was measured in an insufficient number of patients to reach firm conclusions on differences in quality of life between TTF therapy and medical treatment. The highest quality study of TTF combined with medical treatment for recurrent GBM is a post hoc analysis of the EF-14 trial. A high-quality, prospective RCT is needed. The evidence is insufficient to determine the effects of the technology on health outcomes.

## POLICY

Tumor treating fields therapy to treat glioblastoma multiforme is considered **medically necessary** as an adjunct to standard maintenance therapy with temozolomide in patients with newly diagnosed glioblastoma multiforme following initial treatment with surgery, radiotherapy, and/or chemotherapy under the following conditions:

- Adult patients  $\geq 22$  years of age
- Supratentorial tumor
- Karnofsky Performance Status score  $\geq 70\%$
- Patient understands device use, including the requirement for a shaved head, and is willing to comply with use criteria according to the Food and Drug Administration label (see Policy Guidelines).

Tumor treating fields therapy is considered **investigational** in all other conditions, including but not limited to the following situations:

- As an adjunct to standard medical therapy (e.g., bevacizumab, chemotherapy) for patients with progressive or recurrent glioblastoma multiforme
- As an alternative to standard medical therapy for patients with progressive or recurrent glioblastoma multiforme
- For brain metastases
- For cancer in areas other than the brain.

## POLICY GUIDELINES

Progression was defined in the EF-14 trial (Stupp et al [2015, 2017]) according to the MacDonald criteria (tumor growth  $> 25\%$  compared with the smallest tumor area measured in the patient during the trial or appearance of one or more new tumors in the brain that are diagnosed radiologically as glioblastoma multiforme).

The Food and Drug Administration label includes the following notices:

- Patients should use Optune for at least 18 hours a day to get the best response to treatment
- Patients should finish at least four full weeks of therapy to get the best response to treatment. Stopping treatment before four weeks lowers the chances of a response to treatment.

## MEDICARE ADVANTAGE

For Medicare Advantage tumor-treatment fields therapy is considered **not medically necessary**.

## BACKGROUND

### GLIOBLASTOMA MULTIFORME

Glioblastomas, also known as glioblastoma multiforme (GBM), are the most common form of malignant primary brain tumor in adults.<sup>1</sup> GBMs are grade IV astrocytomas, a rapidly progressing and deadly type of glial cell tumor that is often resistant to standard medical therapy (e.g., bevacizumab, chemotherapy). Together, anaplastic astrocytomas and glioblastomas comprise approximately 38% of all brain and central nervous system tumors.<sup>1</sup> The peak incidence for GBM occurs between the ages of 45 and 70 years, with a median age at diagnosis of 64 years. Glioblastomas have the lowest survival rate of any central nervous system tumor; in one report, about a third of patients survived to one year, and the five-year survival rate was around 5%.<sup>2</sup>

### Clinical Context and Therapy Purpose

The purpose of alternating electrical field therapy, more commonly known as TTF therapy, is to provide a treatment option that is better than existing therapies for GBM. TTF has been investigated as an adjunct to temozolomide for the treatment of newly diagnosed GBM and as an alternative or adjunct to medical therapy for progressive or recurrent GBM.

### Treatment of Newly Diagnosed GBM

The primary treatment for patients newly diagnosed with GBM is to resect the tumor to confirm a diagnosis while debulking the tumor to relieve symptoms of increased intracranial pressure or compression. If total resection is not feasible, subtotal resection and open biopsy are options. During surgery, some patients may undergo implantation of the tumor cavity with a carmustine (bis-chloroethylnitrosourea) impregnated wafer. Due to the poor efficacy of local treatment, postsurgical treatment with adjuvant radiotherapy, chemotherapy (typically temozolomide), or a combination of these two therapies is recommended. After adjuvant therapy, patients may undergo maintenance therapy with temozolomide. Maintenance temozolomide is given for five days of every 28-day cycle for six cycles. Response and overall survival rates with temozolomide are higher in patients who have O6-methylguanine-DNA methyltransferase (MGMT) gene promoter methylation.

Prognostic factors for therapy success are age, histology, performance status or physical condition of the patient, and extent of resection. National Comprehensive Cancer Network recommendations include patient age and Karnofsky Performance Status score as important determinants of postsurgical treatment choice.<sup>3</sup> For patients with good performance status, the most aggressive treatment (standard radiotherapy [RT] plus temozolomide) is recommended. For patients with poor performance status, only single treatment cycles or even palliative or supportive care are recommended. Hypofractionated RT is indicated for patients with poor performance status because it is better tolerated, and more patients are able to complete RT.

Treatment of GBM is rarely curative, and tumors will recur essentially all patients.

## Treatment of Recurrent GBM

When disease recurs, additional debulking surgery may be used if the recurrence is localized. Due to radiation tolerances, re-radiation options for patients with recurrent GBM who have previously received initial external-beam radiotherapy are limited. There is no standard adjunctive treatment for recurrent GBM. Treatment options for recurrent disease include various forms of systemic medications such as the antivascular endothelial growth factor drug bevacizumab, alkylating agents such as nitrosoureas (e.g., lomustine, carmustine), or retreatment with temozolomide. Medical therapy is associated with side effects that include hematologic toxicity, headache, loss of appetite, nausea, vomiting, and fatigue. Response rates in recurrent disease are less than 10%, and the progression-free survival rate at six months is less than 20%.<sup>4</sup> There is a need for new treatments that can improve survival in patients with recurrent GBM or reduce the side effects of treatment while retaining survival benefits.

The questions addressed in this protocol are:

- Does TTF, when used as an adjunct to maintenance medical therapy in patients with newly diagnosed GBM, improve the net health outcome?
- Does TTF, when used as an adjunct to medical therapy in patients with recurrent GBM, improve the net health outcome?
- Does TTF, when used as an alternative to medical therapy in patients with recurrent GBM, improve the net health outcome?

The following PICOTS were used to select literature to inform this review.

### Patients

The relevant populations of interest are patients who have newly diagnosed GBM with good performance status or patients with recurrent GBM with good performance status. Newly diagnosed patients would have undergone initial treatment with surgery, RT, and chemotherapy and be receiving maintenance chemotherapy.

### Interventions

TTF therapy is a noninvasive technology intended to treat GBM on an outpatient basis and at home using electrical fields.<sup>4-6</sup> TTF therapy exposes rapidly dividing cancer cells to electric fields of low intensity and intermediate frequency (200 kHz) that alternate in perpendicular orientation. TTF therapy is proposed to inhibit tumor growth by two mechanisms: the arrest of cell proliferation by causing microtubule misalignment in the mitotic spindle of rapidly dividing tumor cells and apoptosis due to movement of macromolecules and organelles during telophase.<sup>5,6</sup> Preclinical studies have indicated that the electric fields may also make the cells more susceptible to chemotherapy.

Optune (formerly NovoTTF-100A System) is the only legally marketed TTF delivery system available in the United States. The portable, battery-powered device is carried in a backpack or shoulder pack while carrying out activities of daily living. For the treatment of glioblastoma,<sup>4</sup> disposable transducer arrays with insulated electrodes are applied to the patient's shaved head. The transducer array layout is typically determined using specialized software. The patient's scalp is re-shaved and the transducer arrays replaced twice a week by the patient, caregiver, or device technician. The device is worn for up to 24 hours a day for the duration of treatment, except for brief periods for personal hygiene and two to three days at the end of each month. The minimum daily treatment is 18 hours. The minimum duration of treatment is one month, with the continuation of treatment available until recurrence.

### Comparators

The following practice is currently being used to make decisions about newly diagnosed GBM: maintenance chemotherapy with temozolomide alone.

The following practices are currently being used to make decisions about recurrent GBM: medical therapy.

TTF therapy might also be compared with palliative or supportive care, where survival rarely exceeds three to five months.<sup>4</sup>

#### Outcomes

The general outcomes of interest are whether TTF improves survival or quality of life during treatment and, because most GBMs recur, the time to tumor recurrence. Measures of cognitive status and quality of life measures are also of interest to determine whether TTF alters the decline in cognition and quality of life that occur with GBM. Also, adverse events of treatment such as side effects of chemotherapy and the possibility of seizures need to be assessed.

#### Timing

Due to the rapid progression of GBM, the time of interest for both progression-free survival and overall survival is months.

#### Setting

The setting is outpatient care by an oncologist or neuro-oncologist.

### REGULATORY STATUS

In April 2011, the NovoTTF-100A™ System (Novocure; assigned the generic name of TTF) was approved by the U.S. Food and Drug Administration (FDA) through the premarket approval process.<sup>7</sup> The FDA-approved label reads as follows: “The NovoTTF-100A System is intended as a treatment for adult patients (22 years of age or older) with confirmed GBM, following confirmed recurrence in an upper region of the brain (supratentorial) after receiving chemotherapy. The device is intended to be used as a stand-alone treatment and is intended as an alternative to standard medical therapy for recurrent GBM after surgical and radiation options have been exhausted.”

In September 2014, the FDA approved Novocure’s request for a product name change from NovoTTF-110A System to Optune®.<sup>8</sup>

In October 2015, the FDA expanded the indication for Optune® in combination with temozolomide to include newly diagnosed GBM.<sup>9</sup> The device was granted priority review status in May 2015 because there was no legally marketed alternative device available for the treatment of newly diagnosed GBM, a life-threatening condition. In July 2016, a smaller, lighter version of the Optune® device, called the Optune® System (NovoTTF-200A System), received FDA approval.

The FDA-approved label for newly diagnosed GBM reads as follows: “This device is indicated as treatment for adult patients (22 years of age or older) with histologically-confirmed glioblastoma multiforme (GBM). Optune™ with temozolomide is indicated for the treatment of adult patients with newly diagnosed, supratentorial glioblastoma following maximal debulking surgery and completion of radiation therapy together with concomitant standard of care chemotherapy.”

FDA product code: NZK.

#### Summary

Glioblastoma multiforme (GBM) is the most common and deadly malignant brain tumor. It has a very poor prognosis and is associated with low quality of life during of treatment. Tumor treatment fields (TTF) therapy is a new, noninvasive technology intended to treat glioblastoma using alternating electric fields.

For individuals who have newly diagnosed GBM on maintenance therapy after initial treatment who receive TTF therapy as an adjunct to standard maintenance therapy, the evidence includes a randomized controlled trial (RCT). Relevant outcomes include overall survival, disease-specific survival, symptoms, functional outcomes, quality of life, and treatment-related morbidity. The EF-14 trial found a significant increase of 2.7 months in progression-free survival and an increase of 4.9 months in overall survival with the addition of TTF therapy to standard maintenance therapy (ie, temozolomide) in patients with newly diagnosed GBM. Although patients were not blinded to treatment assignment, progression-free survival was assessed by blinded evaluators, and the placebo effects on the objective measure of overall survival are expected to be minimal. This technology represents a clinically significant option in the treatment of patients with GBM, for whom options are limited. The evidence is sufficient to determine that the technology results in a meaningful improvement in the net health outcome.

For individuals who have progressive or recurrent GBM who receive TTF therapy as an adjunct or alternative to standard medical therapy, the evidence includes an RCT and nonrandomized comparative studies. Relevant outcomes are overall survival, disease-specific survival, quality of life, and treatment-related morbidity. The single RCT evaluating TTF therapy for recurrent GBM did not show superiority of TTF therapy for the primary outcome (overall survival) compared with physicians' choice chemotherapy. Because no serious adverse effects have been identified with TTF therapy, this raises the possibility that treatment with TTF might reduce the toxicity associated with treatment for recurrent GBM. A reduction in chemotherapy-associated toxicity without loss of efficacy would be considered a net health benefit. However, this RCT is not sufficient to permit conclusions on the efficacy of the device. Because the trial was not designed as a noninferiority trial, no inferences of noninferiority compared with chemotherapy can be made. Also, quality of life assessment was measured in an insufficient number of patients to reach firm conclusions on differences in quality of life between TTF therapy and medical treatment. The highest quality study of TTF combined with medical treatment for recurrent GBM is a post hoc analysis of the EF-14 trial. A high-quality, prospective RCT is needed. The evidence is insufficient to determine the effects of the technology on health outcomes.

## OBJECTIVE

The objective of this evidence review is to determine whether the use of tumor treating fields therapy improves the net health outcome for patients with solid tumors including glioblastoma multiforme.

## POLICY

Tumor treating fields therapy to treat glioblastoma multiforme is considered **medically necessary** as an adjunct to standard maintenance therapy with temozolomide in patients with newly diagnosed glioblastoma multiforme following initial treatment with surgery, radiotherapy, and/or chemotherapy under the following conditions:

- Adult patients ≥18 years of age
- Supratentorial tumor
- Karnofsky Performance Status score ≥70%
- Patient understands device use, including the requirement for a shaved head, and is willing to comply with use criteria according to the Food and Drug Administration label (see Policy Guidelines).

Tumor treating fields therapy is considered **investigational** in all other conditions, including but not limited to the following situations:

- As an adjunct to standard medical therapy (eg, bevacizumab, chemotherapy) for patients with progressive or recurrent glioblastoma multiforme
- As an alternative to standard medical therapy for patients with progressive or recurrent glioblastoma multiforme
- For brain metastases
- For cancer in areas other than the brain.

## POLICY GUIDELINES

Progression was defined in the EF-14 trial (Stupp et al [2015, 2017]) according to the MacDonald criteria (tumor growth >25% compared with the smallest tumor area measured in the patient during the trial or appearance of 1 or more new tumors in the brain that are diagnosed radiologically as glioblastoma multiforme).

The Food and Drug Administration label includes the following notices:

- Patients should use Optune for at least 18 hours a day to get the best response to treatment
- Patients should finish at least 4 full weeks of therapy to get the best response to treatment. Stopping treatment before 4 weeks lowers the chances of a response to treatment.

There are no specific codes for the initial application of this system or instruction on use. The patient reapplies the transducer arrays at home after the initial instruction.

There are HCPCS codes for the system and the transducer arrays:

E0766 Electrical stimulation device, used for cancer treatment, includes all accessories, any type

A4555 Electrode/transducer for use with electrical stimulation device, used for cancer treatment, replacement only.

## BENEFIT APPLICATION

### BlueCard/National Account Issues

State or federal mandates (eg, Federal Employee Program) may dictate that certain U.S. Food and Drug Administration–approved devices, drugs, or biologics may not be considered investigational, and thus these devices may be assessed only on the basis of their medical necessity.

## BACKGROUND

### Glioblastoma Multiforme

Glioblastomas, also known as glioblastoma multiforme (GBM), are the most common form of malignant primary brain tumor in adults.<sup>1</sup> GBMs are grade IV astrocytomas, a rapidly progressing and deadly type of glial cell tumor that is often resistant to standard medical therapy (eg, bevacizumab, chemotherapy). Together, anaplastic astrocytomas and glioblastomas comprise approximately 38% of all brain and central nervous system tumors.<sup>1</sup> The peak incidence for GBM occurs between the ages of 45 and 70 years, with a median age at diagnosis of 64 years. Glioblastomas have the lowest survival rate of any central nervous system tumor; in one report, about a third of patients survived to 1 year, and the 5-year survival rate was around 5%.<sup>2</sup>

### **Clinical Context and Therapy Purpose**

The purpose of alternating electrical field therapy, more commonly known as tumor treating fields (TTF) therapy, is to provide a treatment option that is better than existing therapies for GBM. TTF has been investigated as an adjunct to temozolomide for the treatment of newly diagnosed GBM and as an alternative or adjunct to medical therapy for progressive or recurrent GBM.

### **Treatment of Newly Diagnosed GBM**

The primary treatment for patients newly diagnosed with GBM is to resect the tumor to confirm a diagnosis while debulking the tumor to relieve symptoms of increased intracranial pressure or compression. If total resection is not feasible, subtotal resection and open biopsy are options. During surgery, some patients may undergo implantation of the tumor cavity with a carmustine (bis-chloroethylnitrosourea) impregnated wafer. Due to the poor efficacy of local treatment, postsurgical treatment with adjuvant radiotherapy, chemotherapy (typically temozolomide), or a combination of these 2 therapies is recommended. After adjuvant therapy, patients may undergo maintenance therapy with temozolomide. Maintenance temozolomide is given for 5 days of every 28-day cycle for 6 cycles. Response and overall survival rates with temozolomide are higher in patients who have O<sup>6</sup>-methylguanine-DNA methyltransferase (*MGMT*) gene promoter methylation (see 2.04.113 on *MGMT* promoter methylation for malignant gliomas).

Prognostic factors for therapy success are age, histology, performance status or physical condition of the patient, and extent of resection. National Comprehensive Cancer Network recommendations include patient age and Karnofsky Performance Status score as important determinants of postsurgical treatment choice (see the Supplemental Information section).<sup>3</sup> For patients with good performance status, the most aggressive treatment (standard radiotherapy [RT] plus temozolomide) is recommended. For patients with poor performance status, only single treatment cycles or even palliative or supportive care are recommended. Hypofractionated RT is indicated for patients with poor performance status because it is better tolerated, and more patients are able to complete RT.

Treatment of GBM is rarely curative, and tumors will recur essentially all patients.

### **Treatment of Recurrent GBM**

When disease recurs, additional debulking surgery may be used if the recurrence is localized. Due to radiation tolerances, re-radiation options for patients with recurrent GBM who have previously received initial external-beam radiotherapy are limited. There is no standard adjunctive treatment for recurrent GBM. Treatment options for recurrent disease include various forms of systemic medications such as the antivascular endothelial growth factor drug bevacizumab, alkylating agents such as nitrosoureas (eg, lomustine, carmustine), or retreatment with temozolomide. Medical therapy is associated with side effects that include hematologic toxicity, headache, loss of appetite, nausea, vomiting, and fatigue. Response rates in recurrent disease are less than 10%, and the progression-free survival rate at 6 months is less than 20%.<sup>4</sup> There is a need for new treatments that can improve survival in patients with recurrent GBM or reduce the side effects of treatment while retaining survival benefits.

The questions addressed in this evidence review are:

- Does TTF, when used as an adjunct to maintenance medical therapy in patients with newly diagnosed GBM, improve the net health outcome?
- Does TTF, when used as an adjunct to medical therapy in patients with recurrent GBM, improve the net health outcome?
- Does TTF, when used as an alternative to medical therapy in patients with recurrent GBM, improve the net health outcome?

The following PICOTS were used to select literature to inform this review.

### **Patients**

The relevant populations of interest are patients who have newly diagnosed GBM with good performance status or patients with recurrent GBM with good performance status. Newly diagnosed patients would have undergone initial treatment with surgery, RT, and chemotherapy and be receiving maintenance chemotherapy.

### **Interventions**

TTF therapy is a noninvasive technology intended to treat GBM on an outpatient basis and at home using electrical fields.<sup>4-6</sup> TTF therapy exposes rapidly dividing cancer cells to electric fields of low intensity and intermediate frequency (200 kHz) that alternate in perpendicular orientation. TTF therapy is proposed to inhibit tumor growth by 2 mechanisms:

**Case 1:20-cv-00194-WCG Filed 04/28/20 Page 380 of 1212 Document 11-2** 1859

the arrest of cell proliferation by causing microtubule misalignment in the mitotic spindle of rapidly dividing tumor cells and apoptosis due to movement of macromolecules and organelles during telophase.<sup>5,6</sup> Preclinical studies have indicated that the electric fields may also make the cells more susceptible to chemotherapy.

Optune (formerly NovoTTF-100A System) is the only legally marketed TTF delivery system available in the United States. The portable, battery-powered device is carried in a backpack or shoulder pack while carrying out activities of daily living. For the treatment of glioblastoma, 4 disposable transducer arrays with insulated electrodes are applied to the patient's shaved head. The transducer array layout is typically determined using specialized software. The patient's scalp is re-shaved and the transducer arrays replaced twice a week by the patient, caregiver, or device technician. The device is worn for up to 24 hours a day for the duration of treatment, except for brief periods for personal hygiene and 2 to 3 days at the end of each month. The minimum daily treatment is 18 hours. The minimum duration of treatment is 1 month, with the continuation of treatment available until recurrence.

### **Comparators**

The following practice is currently being used to make decisions about newly diagnosed GBM: maintenance chemotherapy with temozolomide alone.

The following practices are currently being used to make decisions about recurrent GBM: medical therapy.

TTF therapy might also be compared with palliative or supportive care, where survival rarely exceeds 3 to 5 months.<sup>4</sup>

### **Outcomes**

The general outcomes of interest are whether TTF improves survival or quality of life during treatment and, because most GBMs recur, the time to tumor recurrence. Measures of cognitive status and quality of life measures are also of interest to determine whether TTF alters the decline in cognition and quality of life that occur with GBM. Also, adverse events of treatment such as side effects of chemotherapy and the possibility of seizures need to be assessed.

### **Timing**

Due to the rapid progression of GBM, the time of interest for both progression-free survival and overall survival is months.

### **Setting**

The setting is outpatient care by an oncologist or neuro-oncologist.

### **Regulatory Status**

In April 2011, the NovoTTF-100A™ System (Novocure; assigned the generic name of TTF) was approved by the U.S. Food and Drug Administration (FDA) through the premarket approval process.<sup>7</sup> The FDA-approved label reads as follows: "The NovoTTF-100A System is intended as a treatment for adult patients (22 years of age or older) with confirmed GBM, following confirmed recurrence in an upper region of the brain (supratentorial) after receiving chemotherapy. The device is intended to be used as a stand-alone treatment and is intended as an alternative to standard medical therapy for recurrent GBM after surgical and radiation options have been exhausted."

In September 2014, FDA approved Novocure's request for a product name change from NovoTTF-110A System to Optune®.<sup>8</sup>

In October 2015, FDA expanded the indication for Optune® in combination with temozolomide to include newly diagnosed GBM.<sup>9</sup> The device was granted priority review status in May 2015 because there was no legally marketed alternative device available for the treatment of newly diagnosed GBM, a life-threatening condition. In July 2016, a smaller, lighter version of the Optune® device, called the Optune® System (NovoTTF-200A System), received FDA approval.

The FDA-approved label for newly diagnosed GBM reads as follows: "This device is indicated as treatment for adult patients (22 years of age or older) with histologically-confirmed glioblastoma multiforme (GBM). Optune™ with temozolomide is indicated for the treatment of adult patients with newly diagnosed, supratentorial glioblastoma following maximal debulking surgery and completion of radiation therapy together with concomitant standard of care chemotherapy."

FDA product code: NZK.

### **RATIONALE**

This evidence review was created in August 2013 and has been updated regularly with searches of the MEDLINE database. The most recent literature update was performed through April 5, 2018.

Evidence reviews assess the clinical evidence to determine whether the use of a technology improves the net health outcome. Broadly defined, health outcomes are length of life, quality of life, and ability to function—including benefits and harms. Every clinical condition has specific outcomes that are important to patients and to managing the course of that condition. Validated outcome measures are necessary to ascertain whether a condition improves or worsens; and whether the magnitude of that change is clinically significant. The net health outcome is a balance of benefits and harms.

To assess whether the evidence is sufficient to draw conclusions about the net health outcome of a technology, 2 domains are examined: the relevance and the quality and credibility. To be relevant, studies must represent one or more intended clinical use of the technology in the intended population and compare an effective and appropriate alternative at a comparable intensity. For some conditions, the alternative will be supportive care or surveillance. The quality and credibility of the evidence depend on study design and conduct, minimizing bias and confounding that can generate incorrect findings. The randomized controlled trial (RCT) is preferred to assess efficacy; however, in some circumstances, nonrandomized studies may be adequate. RCTs are rarely large enough or long enough to capture less common adverse events and long-term effects. Other types of studies can be used for these purposes and to assess generalizability to broader clinical populations and settings of clinical practice.

For this review, 3 indications are evaluated: (1) tumor treating fields (TTF) as an adjunct to maintenance chemotherapy in newly diagnosed patients following initial treatment with surgery, radiotherapy and chemotherapy and (2) TTF as an adjunct or (3) alternative to medical therapy (eg, bevacizumab, chemotherapy) in progressive or recurrent glioblastoma multiforme (GBM).

### Study Selection

The PICOTS was used to select relevant studies.

- To assess efficacy outcomes, comparative controlled prospective trials were sought, with a preference for RCTs.
- To assess longer term outcomes and adverse events, single-arm studies that capture longer periods of follow-up and/or larger populations were sought.
- Within each category of study design, studies with larger sample size studies and longer duration were sought.

## TTF Therapy as an Adjunct to Standard Maintenance Care for Newly Diagnosed GBM

### Randomized Controlled Trials

Stupp et al (2017) published results of the EF-14 multicenter, open-label phase 3 RCT that evaluated maintenance therapy with TTF for newly diagnosed GBM.<sup>10</sup> The trial included 695 patients from 83 sites who had supratentorial GBM and had completed standard treatment consisting of biopsy or surgical resection followed by radiotherapy and chemotherapy (see Table 1). A Karnofsky Performance Status (KPS) score of 70 or higher was an additional inclusion criterion to ensure independence in activities of daily living, and patients with rapidly progressing GBM following radiochemotherapy were excluded from the trial. Patients were randomized in a 2:1 fashion to TTF plus maintenance temozolomide or maintenance temozolomide alone.

All patients were seen monthly for follow-up. Quality of life (QOL) was assessed every 3 months, and magnetic resonance imaging (MRI) was performed every 2 months until tumor progression. Tumor progression on MRI was adjudicated by a central review committee blinded to treatment group. The primary outcome was progression-free survival (PFS), and the secondary outcome was overall survival (OS). The analysis was by intention-to-treat, including 26 patients from the control arm who crossed over to TTF following the planned interim analysis.

In 2014, an independent data and safety monitoring board concluded from the planned interim analysis that the trial met its predefined boundaries for success (improvement in PFS and OS) and recommended trial termination. The Food and Drug Administration approved the trial termination, and the trial was closed to recruitment with 695 of the planned 700 participants randomized. Control arm participants were allowed to cross over to the experimental treatment at this time. The interim analysis, which the Food and Drug Administration considered for the 2015 expanded approval of Optune, was published by Stupp et al (2015).<sup>11</sup> At the time of the interim analysis, data were available for 210 patients randomized to TTF plus temozolomide and 105 patients to temozolomide alone. Follow-up of the remainder of the 695 enrolled patients continued after enrollment was closed.

**Table 1. Key Randomized Controlled Trial Characteristics for Newly Diagnosed Glioblastoma**

Study; Trial	Countries	Sites	Dates	Participants	Interventions	
					Active	Comparator
Stupp et al (2017) <sup>10</sup> ; EF-14	U.S., E.U., South Korea, Israel	83	2009-2016	<ul style="list-style-type: none"> <li>• 695 newly diagnosed with GBM and treated by radiochemotherapy</li> <li>• KPS score <math>\geq 70</math></li> </ul>	TTF >18 h/d plus maintenance temozolomide (n=466)	Maintenance temozolomide alone (5 d every 28 d for 6 cycles) (n=229)

GBM: glioblastoma multiforme; h/d; hours per day; KPS: Karnofsky Performance Status; TTF: tumor treatment fields.

Results of the final analysis of the EF-14 trial were similar to the interim analysis and are shown in Table 2. Both PFS and OS improved with the addition of TTF therapy to standard maintenance chemotherapy (ie, temozolomide). PFS increased by 2.7 mo ( $p < 0.001$ ) and OS increased by 4.9 mo ( $p < 0.001$ ) in the TTF group. The time to a decrease in mental function was 2.5 months longer with TTF therapy ( $p < 0.01$ ).

There was a similar percentage of dropouts at the final analysis—with 49 (11%) patients in the TTF group and 27 (12%) patients in the temozolomide alone group. More treatment cycles with temozolomide were administered in the TTF group (median, 6 for TTF group vs 5 for controls), a finding that is consistent with the longer PFS. Rates of adverse events were similar between the groups, including rates of seizures. In secondary analysis of patients who had not progressed, there

was no reduction in health-related quality of life with TTF compared with temozolomide alone aside from “itchy skin”.<sup>12</sup> Interpretation of this result is limited by the low percentage of patients who completed the health-related quality of life assessments at follow-up (65.8% of the 655 patients alive at 3 months and 41.7% of the 473 patients alive at 12 months). A mixed-model analysis, which accounts for missing data, confirmed the results of the mean change from baseline analysis.

**Table 2. Key Randomized Controlled Trial Results for Newly Diagnosed Glioblastoma**

Study	Final N (%)	Median PFS (95% CI), mo	Median OS (95% CI), mo	Systemic Adverse Events, n (%)	Seizures, n (%)	Time to 6-Point Decline in MMSE Score (95% CI), mo
Stupp et al (2017) <sup>10</sup>						
TTF + temozolomide	417 (89)	6.7 (6.1 to 8.1)	20.9 (19.3 to 22.7)	218 (48)	26 (6)	16.7 (14.7 to 19.0)
Temozolomide alone	202 (88)	4.0 (3.8 to 4.4)	16.0 (14.0 to 18.4)	94 (44)	13 (6)	14.2 (12.7 to 17.0)
HR (95% CI)		0.63 (0.52 to 0.76)	0.63 (0.53 to 0.76)			0.79 (0.66 to 0.95)
P value		<0.001	<0.001	0.58		0.01

CI: confidence interval; HR: hazard ratio; MMSE: Mini-Mental State Examination; OS: overall survival; PFS: progression-free survival; TTF: tumor treatment fields.

Tables 3 and 4 display notable gaps identified in this trial, the major limitation is the lack of patient blinding to treatment assignment. However, PFS was assessed by investigators who were blinded to treatment and placebo effects on OS were expected to be minimal. Investigators considered it practically unfeasible (due to the heat and current of the TTF therapy) and ethically unacceptable to submit the control patients to repeated shaving of the head and continuous wear of a sham device over many months.

**Table 3. Relevance Gaps**

Study; Trial	Population <sup>a</sup>	Intervention <sup>b</sup>	Comparator <sup>c</sup>	Outcomes <sup>d</sup>	Follow-Up <sup>e</sup>
Stupp et al (2017) <sup>10</sup> ; EF-14			3. Possible differences in post-progression treatment affecting overall survival		

The evidence gaps stated in this table are those notable in the current review; this is not a comprehensive gaps assessment.

<sup>a</sup> Population key: 1. Intended use population unclear; 2. Clinical context is unclear; 3. Study population is unclear; 4. Study population not representative of intended use.

### Section Summary: TTF Therapy as an Adjunct to Standard Maintenance Care for Newly Diagnosed GBM

The final analysis of the EF-14 trial, which included 695 patients from 83 sites, found a statistically and clinically significant increase of 2.7 months in PFS and an increase of 4.9 months in OS with the addition of TTF therapy to standard maintenance therapy (ie, temozolomide) in patients with newly diagnosed GBM. There was no sham control, and patients were not blinded to treatment assignment, but PFS was assessed by blinded evaluators, and placebo effects on the

objective measure of OS were likely to be minimal. There was no evidence of a negative impact of TTF therapy on health-related quality of life, except for itchy skin from the transducers.

## TTF Therapy as an Adjunct or Alternative to Medical Therapy for Progressive or Recurrent GBM

### Randomized Controlled Trials

The 2011 Food and Drug Administration approval of the NovoTTF-100A System (now called Optune) was based on a phase 3 multinational RCT (EF-11), results of which were published by Stupp et al (2012).<sup>4</sup> This trial compared TTF therapy alone with physician's choice medical therapy in 237 adults who had relapsed or progressive glioblastoma (see Table 5). Patients had failed conventional treatment with radiotherapy, chemotherapy, and/or surgery, and more than 80% of participants had failed 2 or more prior chemotherapy regimens. In this trial, the term chemotherapy also applied to targeted agents such as bevacizumab. Patient characteristics and performance of additional post-recurrence debulking surgery were similar in the 2 groups.

**Table 5. Summary of Key Randomized Controlled Trial Characteristics for Progressive or Recurrent Glioblastoma**

Study; Trial	Countries	Sites	Dates	Participants	Interventions	
					Active	Comparator
Stupp et al (2012) <sup>4</sup> ; EF-11	U.S., E.U., Israel	28	1987-2013	<ul style="list-style-type: none"> <li>237 adults with relapsed or progressive supratentorial glioblastoma</li> <li>KPS score <math>\geq 70\%</math></li> </ul>	120 patients treated with TTF alone, 93 (78%) completed 1 cycle	117 patients treated with physician's choice of medical therapy <sup>a</sup>

EU: European Union; KPS: Karnofsky Performance Status; TTF: tumor treating fields.

<sup>a</sup> Medical therapy included bevacizumab, irinotecan, nitrosoureas, platinum-based chemotherapy (ie, carboplatin); temozolomide; or a combination of procarbazine, chloroethyl ether, and vincristine.

Participants were followed monthly, including laboratory tests. MRI images were evaluated at 2, 4, and 6 months from initiation of treatment, with subsequent MRIs performed according to local practice until disease progression. QOL questionnaires were completed every 3 months. Medical follow-up continued for 2 months after disease progression. Monthly telephone interviews with participants' caregivers were used to assess mortality rates. The primary end point was OS. Secondary end points included PFS, the percentage of patients with PFS at 6 months, time to progression, 1-year survival rate, QOL, and radiologic response. All end points were evaluated using intention-to-treat analysis.

The trial did not reach its primary end point of improved survival compared with active medical therapy (see Table 6). With a median follow-up of 39 months, 93% of patients had died. There was not a statistically significant difference in survival rates at 1, 2, and 3 years between groups. Patients in the TTF group did not, however, suffer the typical systemic side effects of chemotherapy. The most common adverse event in the TTF group was grade 1 and 2 contact dermatitis on the scalp, which resolved with topical corticosteroids and did not require treatment breaks. Control participants experienced grade 2, 3, or 4 events by organ system related to the pharmacologic activity of chemotherapy agents used. Hematologic events of grade 2 or greater were observed in 17% of chemotherapy patients compared with 3% of TTF patients. Gastrointestinal disorders of grade 2 or greater were identified in 17% of chemotherapy patients compared with 4% of TTF patients. Severe (grades 3-4) hematologic and gastrointestinal toxicity was observed in 7% of chemotherapy controls compared with 1% of the TTF group.

Longitudinal QOL data, available in 63 (27%) participants, showed no meaningful differences between groups for the domains of global health and social functioning. However, cognitive and emotional functioning domains favored TTF therapy. Symptom scale analysis was by treatment-associated toxicity; appetite loss, diarrhea, constipation, nausea, and vomiting were directly related to the chemotherapy administration.

The trial had a number of limitations (see Tables 7 and 8), that included lack of blinding and high loss to follow-up. Discontinuation of TTF therapy occurred in 22% of patients due to noncompliance or inability to handle the device, usually within the first few days. In the control group, 21 (18%) patients did not return to the treatment site, and details on disease progression and toxicity were not available. Longitudinal QOL could be analyzed only for 27% of patients who remained on study therapy for 3 months. The trial was designed as a superiority trial and did not provide adequate evidence of noninferiority.

## Nonrandomized Comparative Studies

Kesari et al (2017) conducted a post hoc analysis of the EF-14 trial (see Stupp et al [2017] above) to evaluate the efficacy of TTF in patients who had the first recurrence.<sup>13</sup> Some patients in the temozolomide alone group crossed over to receive TTF plus chemotherapy after the first recurrence, resulting in 144 patients who received TTF fields plus chemotherapy and 60 patients who received chemotherapy alone for recurrent GBM (see Table 9). Patient characteristics and second-line treatments were well-balanced between the groups, with bevacizumab the most common second-line therapy. The median OS in patients treated with systemic therapy alone was 9.2 months (see Table 10). In comparison, the group of patients who received TTF therapy in addition to systemic therapy had a median OS of 11.8 months (p=0.043).

A registry study published Mrugala et al (2014) assessed OS data from patients who received NovoTTF therapy in a real-world, clinical practice setting (see Table 9).<sup>14</sup> Concurrent treatment was not captured in the registry, and it is possible that some patients received combination therapy. Median OS in the PRiDe clinical practice dataset (9.6 mo) was reported as superior to that attained in the EF-11 pivotal trial (6.6 mo, p<0.001) (see Table 10). More patients in the PRiDe registry were treated for first recurrence (33% vs 9%), and more had received bevacizumab as prior therapy (55% vs 19%). The PRiDe investigators reported no novel or unexpected treatment-related adverse events compared with the EF-11 trial.

CI: confidence interval; OS: overall survival, TTF: tumor treating fields.

Post hoc analyses of the EF-11 pivotal trial have been reported. Wong et al (2014) published a subgroup analysis to determine characteristics of responders and nonresponders in the active treatment and active treatment control.<sup>15</sup> They found that responders had a lower grade of histology and lower daily dexamethasone use than nonresponders. A second post hoc analysis by Kanner et al (2014) of the EF-11 pivotal trial data was performed to evaluate OS among patients who finished at least 1 complete course of TTF or chemotherapy.<sup>16</sup> The investigators reported that median OS was 7.7 months in the TTF group compared with 5.9 months in the chemotherapy group ( $p=0.009$ ). These post hoc analyses are considered to be hypothesis-generating.

### Section Summary: TTF Therapy as an Adjunct or Alternative to Chemotherapy for Progressive or Recurrent GBM

The single RCT for TTF as an alternative to chemotherapy reported that outcomes following TTF therapy were similar to outcomes following standard chemotherapy. However, this RCT is not sufficient to permit conclusions on the efficacy of the device. The noninferiority of TTF compared with chemotherapy might be considered a sufficient health benefit, if TTF reduced treatment toxicity. However, because the trial was not designed as a noninferiority trial no inferences of noninferiority compared with chemotherapy can be made. Physician's choice therapy during the trial was heterogeneous, although analysis indicated that survival was not affected by choice of chemotherapy. More patients in the TTF group than in the control group did not complete the treatment course. The number of patients who contributed QOL data was approximately one-quarter of total enrollment, and the self-reported QOL indicators might have been subject to bias due to the lack of blinding.

A nonrandomized post hoc evaluation of the EF-14 trial suggests that TTF may improve survival when combined with chemotherapy for recurrent GBM. This analysis should be considered hypothesis-generating, and further study in high-quality RCTs is needed.

### Summary of Evidence

For individuals who have newly diagnosed GBM on maintenance therapy after initial treatment who receive TTF therapy as an adjunct to standard maintenance therapy, the evidence includes an RCT. Relevant outcomes include overall survival, disease-specific survival, symptoms, functional outcomes, quality of life, and treatment-related morbidity. The EF-14 trial found a significant increase of 2.7 months in progression-free survival and an increase of 4.9 months in overall survival with the addition of TTF therapy to standard maintenance therapy (ie, temozolomide) in patients with newly diagnosed GBM. Although patients were not blinded to treatment assignment, progression-free survival was assessed by blinded evaluators, and the placebo effects on the objective measure of overall survival are expected to be minimal. This technology represents a clinically significant option in the treatment of patients with GBM, for whom options are limited. The evidence is sufficient to determine that the technology results in a meaningful improvement in the net health outcome.

For individuals who have progressive or recurrent GBM who receive TTF therapy as an adjunct or alternative to standard medical therapy, the evidence includes an RCT and nonrandomized comparative studies. Relevant outcomes are overall survival, disease-specific survival, quality of life, and treatment-related morbidity. The single RCT evaluating TTF therapy for recurrent GBM did not show superiority of TTF therapy for the primary outcome (overall survival) compared with physicians' choice chemotherapy. Because no serious adverse effects have been identified with TTF therapy, this raises the possibility that treatment with TTF might reduce the toxicity associated with treatment for recurrent GBM. A reduction in chemotherapy-associated toxicity without loss of efficacy would be considered a net health benefit. However, this RCT is not sufficient to permit conclusions on the efficacy of the device. Because the trial was not designed as a noninferiority trial, no inferences of noninferiority compared with chemotherapy can be made. Also, quality of life assessment was measured in an insufficient number of patients to reach firm conclusions on differences in quality of life between TTF therapy and medical treatment. The highest quality study of TTF combined with medical treatment for recurrent GBM is a post hoc analysis of the EF-14 trial. A high-quality, prospective RCT is needed. The evidence is insufficient to determine the effects of the technology on health outcomes.

### SUPPLEMENTAL INFORMATION

#### Clinical Input From Physician Specialty Societies and Academic Medical Centers

While the various physician specialty societies and academic medical centers may collaborate with and make recommendations during this process, through the provision of appropriate reviewers, input received does not represent an endorsement or position statement by the physician specialty societies or academic medical centers, unless otherwise noted.

In response to requests, input was received from 3 physician specialty societies (one of which provided 6 responses and 2 of which provided 1 response each) and 1 academic medical center (total of 9 individual responses) while this policy was under review in 2016. There was majority support, but not consensus, for the use of tumor treatment fields therapy as an adjunct to maintenance treatment following initial therapy for glioblastoma multiforme. There was mixed support for the use of tumor treatment fields as an alternative to chemotherapy in advanced or recurrent glioblastoma multiforme.

### Practice Guidelines and Position Statements

National Comprehensive Cancer Network guidelines on central nervous system cancers (v.1.2018) include recommendations for the treatment of glioblastoma (see Table 11).<sup>3</sup> For the initial treatment of patients with glioblastoma with good performance status and either methylated or unmethylated or indeterminate O<sup>6</sup>-methylguanine-DNA methyltransferase promotor status, treatment with standard brain radiotherapy plus concurrent temozolomide and adjuvant temozolomide plus alternating electric field therapy is a category 1 recommendation. Alternating electric currents therapy is only an option for patients with supratentorial disease. Consideration of alternating electric field therapy for recurrent glioblastoma is a category 2B recommendation.

**Table 11. Guidelines for Adjuvant Treatment of Glioblastoma, by Age and Performance Status**

Age, y	KPS Score, %	Treatment Options	Category
≤70	≥60	<ul style="list-style-type: none"> <li>Standard RT plus concurrent and adjuvant temozolomide plus TTF</li> <li>Standard RT plus concurrent and adjuvant temozolomide</li> </ul>	1

KPS: Karnofsky Performance Status; RT: radiotherapy; TTF: tumor treating fields.

### U.S. Preventive Services Task Force Recommendations

Not applicable.

### Medicare National Coverage

There is no national coverage determination. In the absence of a national coverage determination, coverage decisions are left to the discretion of local Medicare carriers.

### Ongoing and Unpublished Clinical Trials

Some currently unpublished trials that might influence this review are listed in Table 12. Of particular note are the phase 3 trials evaluating TTF therapy in non-small-cell lung cancer and pancreatic cancer. TTF therapy is an active area of research for mechanisms underlying its effects on cancer cells.

# TUMOR-TREATMENT FIELDS THERAPY FOR GLIOBLASTOMA (REQUIRES PREAUTHORIZATION) VIII.9

## DESCRIPTION

Glioblastomas, also known as glioblastoma multiforme (GBM), are the most common form of malignant primary brain tumor in adults. They comprise approximately 15% of all brain and central nervous system tumors, and more than 50% of all tumors that arise from glial cells. The peak incidence for GBM occurs between the ages of 45 and 70 years. GBMs are grade IV astrocytoma and are often resistant to standard chemotherapy. According to the National Comprehensive Cancer Network, GBM is the "deadliest brain tumor with only a third of patients surviving for 1 year and less than 5% living beyond 5 years.

Alternating electric fields, generated by insulated electrodes, have been reported to exhibit inhibitory effect on the growth rate of variety of human and rodent tumor cell lines as well as malignant tumors in animals. This non-thermal effect selectively affects dividing cells while quiescent cells are left intact.

## POLICY

I. Tumor treatment fields therapy may be considered **medically necessary** as combination therapy for glioblastoma when **ALL** of the following are met:

- A. the member is 18 years of age or older **AND**
- B. the member is newly diagnosed with supratentorial, histologically confirmed glioblastoma **AND**
- C. will be used with temozolomide (TMZ) following initial treatment with surgery, chemotherapy or radiation.

8/13/2018  
II. Tumor treatment fields therapy may be considered **medically necessary** as monotherapy for glioblastoma when **ALL** of the following are met:

- A. the member is 18 years of age or older **AND**
- B. the member has recurrence of supratentorial, histologically confirmed glioblastoma **AND**
- C. following initial treatment with chemotherapy or radiation

III. Tumor treatment fields therapy for all other indications is considered **investigational** as the clinical effectiveness has not been established.

## BACKGROUND

Glioblastomas, also known as glioblastoma multiforme (GBM), are the most common form of malignant primary brain tumor in adults. They comprise approximately 15% of all brain and central nervous system tumors and more than 50% of all tumors that arise from glial cells.<sup>1</sup> The peak incidence for GBM occurs between the ages of 45 and 70 years. GBMs are grade IV astrocytomas, the most deadly type of glial cell tumor, and are often resistant to standard chemotherapy.<sup>1</sup> According to the National Comprehensive Cancer Network, GBM is the "deadliest brain tumor with only a third of patients surviving for 1 year and less than 5% living beyond 5 years."<sup>2</sup>

The primary treatment for GBM is debulking surgery to remove as much of the tumor as possible. At that time, some patients may undergo implantation of the tumor cavity with a carmustine (bischloroethylnitrosourea [BCNU])?impregnated wafer.<sup>2</sup> Depending on the patient's physical condition, adjuvant radiotherapy, chemotherapy (typically temozolomide), or a combination of the 2 are sometimes given. After adjuvant therapy, some patients may undergo maintenance therapy with temozolomide.

No standard treatment exists for recurrent GBM. In patients with disease that recurs after these initial therapies, additional debulking surgery may be used if recurrence is localized. Other treatment options for recurrent disease include various forms of systemic medications such as bevacizumab, bevacizumab plus chemotherapy (eg, irinotecan, BCNU/chloroethylnitrosourea [CCNU], temozolomide), temozolomide, nitrosourea, PCV (procarbazine, CCNU, vincristine), cyclophosphamide, and platinum-based agents.<sup>2</sup> External beam radiotherapy (EBRT) also may be used to treat recurrent GBM. Response rates in recurrent disease are less than 10%, and progression-free survival rates at 6 months are less than 20%.<sup>2,3</sup>

TTF therapy is a new, noninvasive technology that is intended to treat GBM on an outpatient basis using electrical fields.<sup>3-5</sup> TTF therapy exposes cancer cells to alternating electric fields of low intensity and intermediate frequency, which are purported to both selectively inhibit tumor growth and reduce tumor angiogenesis. TTF are proposed to inhibit rapidly dividing tumor cells by 2 mechanisms, arrest of cell proliferation and destruction of cells while undergoing division.<sup>4,5</sup>

The NovoTTF-100A™ System (Novocure, Haifa, Israel) has received FDA marketing approval to deliver TTF therapy. TTF therapy via the NovoTTF-100A™ System is delivered by a battery-powered, portable device that generates the fields via disposable electrodes that are noninvasively attached to the patient's shaved scalp over the site of the

tumor.<sup>3,4</sup> The device is used by the patient at home on a continuous basis (20-24 h/d) for the duration of treatment, which can last for several months. Patients can carry the device in a backpack or shoulder pack while carrying out activities of daily living.<sup>3,4</sup>

## RATIONALE

This evidence review was created in August 2013 and updated periodically through literature reviews, most recently through July 8, 2015. No new studies were identified that would change the conclusions of the evidence review. Following is a summary of the key literature.

### Randomized Controlled Trials

The U.S. Food and Drug Administration (FDA) approval of the NovoTTF-100A system was based on a phase 3, multinational prospective randomized controlled trial (RCT) (EF11) which was published in 2012 by Stupp et al. The Stupp study, which was sponsored and funded by the manufacturer of the device (Novocure), compared tumor-treatment fields (TTF) therapy (delivered by the NovoTTF-100A System) with the best standard of care chemotherapy (active control).<sup>3</sup> Twenty-eight clinical centers (across 7 countries) enrolled 237 adult participants with relapsed or progressive glioblastoma multiforme (GBM), despite conventional radiotherapy. Other prior treatments may have included surgery and/or chemotherapy. Patient characteristics were balanced in both groups, with median age of 54 years and median Karnofsky Performance Status score of 80%. More than 80% of participants had failed 2 or more prior chemotherapy regimens ( $\geq$  second recurrence), and 20% had failed bevacizumab before study enrollment.

Two hundred thirty-seven patients were randomized in a 1:1 ratio to receive TTF therapy only (n=120) or active control (n=117). The choice of chemotherapy regimens varied, reflecting local practice at each of the participating clinical centers. Chemotherapy agents considered as active control during the trial included platinum-based chemotherapy (ie, carboplatin); nitrosoureas; procarbazine; combination of procarbazine, lomustine and vincristine (PCV); temozolomide; and bevacizumab. For patients assigned to the TTF group, uninterrupted treatment was recommended, although patients were allowed to take treatment breaks of up to 1 hour, twice per day, for personal needs (eg, shower). In addition, patients assigned to the TTF group were allowed to take 2 to 3 days off treatment at the end of each of 4-week period (which is the minimal required treatment duration for TTF therapy to reverse tumor growth). A period of 28 days of treatment with TTF was considered 1 full treatment course.

The primary study end point in this RCT was overall survival (OS).<sup>3</sup> Secondary end points included progression-free survival (PFS) at 6 months, TTP, 1-year survival rate, quality of life (QOL), and radiologic response. Participants were seen in clinic monthly, and magnetic resonance imaging (MRI) was performed after 2, 4, and 6 months from initiation of treatment, with subsequent MRI done according to local practice until disease progression. Medical follow-up continued for 2 months after disease progression. Monthly telephone interviews with participants' caregivers were used to assess participant mortality rates.

Ninety-seven percent (116) of 120 participants in the TTF group started treatment and 93 participants (78%) completed 1 cycle (4 weeks) of therapy. Discontinuation of TTF therapy occurred in 27 participants (22%) due to noncompliance or the inability to handle the device.<sup>3</sup> For each TTF treatment month, the median compliance was 86% (range, 41%-98%), which equaled a mean use of 20.6 hours per day. In the active control group, 113 (97%)

of the 117 assigned participants received chemotherapy and all except 1 individual completed a full treatment course. Twenty-one participants (18%) in the active control group did not return to the treating site and details on disease progression and toxicity were not available.

This RCT did not reach its primary end point of improved survival compared with active chemotherapy. With a median follow-up of 39 months, 220 participants (93%) had died. Median survival was 6.6 months in the TTF group compared with 6.0 months in the active control group (hazard ratio [HR], 0.86; 95% confidence interval [CI], 0.66 to 1.12;  $p=0.27$ ). For both groups, 1-year survival was 20%. The survival rates for 2- and 3-year survival were 8% and 4%, respectively, for the TTF group versus 5% and 1%, respectively, for the active control group. PFS rate at 6 months was 21.4% in the TTF group, compared with 15.1% in the active control group ( $p=0.13$ ). Objective radiologic responses (partial and complete response) were noted in 14 participants in the TTF group and 7 in the active control group, with a calculated response rate of 14.0% (95% CI, 7.9% to 22.4%) versus 9.6% (95% CI, 3.9% to 18.8%), respectively. Sixteen percent of the TTF participants had grade 1 and 2 contact dermatitis on the scalp, which resolved with topical corticosteroids. Active control participants experienced grade 2 to 4 events by organ system related to the pharmacologic activity of chemotherapy agents used; severe (grades 3 and 4) toxicity was observed in 3% of participants.

Longitudinal QOL data were available in 63 participants (27%). There were no meaningful differences observed between the groups in the domains of global health and social functioning. However, cognitive, emotional, and role functioning favored TTF therapy, whereas physical functioning favored chemotherapy. Symptom scale analysis was in accordance to treatment-associated toxicity; appetite loss, diarrhea, constipation, nausea, and vomiting were directly related to the chemotherapy administration. Increased pain and fatigue was reported in the chemotherapy-treated patients and not in the TTF group.

In summary, this RCT failed to demonstrate the primary end point of improved survival with TTF therapy in comparison with chemotherapy.<sup>3,9</sup> Limitations of the trial included a somewhat heterogeneous patient population, with participants included after progression of 1 or several lines of chemotherapy, as well as the use of different chemotherapy regimens in the control group. Another limitation is the absence of a placebo/supportive care arm. In the setting of advanced disease, the supportive care arm would have been useful to gauge the safety and efficacy of treatment for both groups of patients. Treatments used in the active control arm (best standard of care chemotherapy) in the recurrent disease setting have previously demonstrated limited efficacy, thus limiting the ability to determine the true treatment effect of TTF. Data from a trial of TTF versus placebo, or TTF plus standard chemotherapy versus standard chemotherapy alone would therefore provide a better assessment of treatment efficacy. The latter study design is being used in an ongoing trial of TTF therapy in the treatment of patients with newly diagnosed GBM (see Ongoing and Unpublished Clinical Trials section).

A further limitation was high dropout rates in both groups. For example, over 20% of participants in the active control group were lost at follow-up, and this degree of the number of dropouts may have underestimated the toxicity evaluation in this group. Similarly, over 20% of participants in the TTF arm discontinued treatment within a few days due to noncompliance or inability to handle the device. This implies that compliance might be an issue with TTF, because it requires the patient to continuously wear transducers on the shaved head. Finally, the number of patients who completed the QOL data was approximately one quarter of total enrollment, and the self-reported QOL indicators may have been subject to bias due to the lack of blinding.<sup>3,6</sup>

Wong et al published a subgroup analysis of the previously described RCT to determine characteristics of responders and nonresponders in the treatment and active control groups.<sup>10</sup> Tumor response was assessed by the Macdonald criteria. More patients in the TTF arm were considered responders (14/120 vs 7/117 in the chemotherapy arm.) Median response time was longer for those in the TTF arm than the chemotherapy arm (7.3 months vs 5.6 months,  $p=0.001$ ), and the overall survival was longer in the TTF arm (12.1 months vs 10.5 months,  $p=0.001$ ).<sup>10</sup>

TTF arm ( $p < 0.001$ ) but not in the chemotherapy arm ( $p = 0.29$ ). Compared with the chemotherapy arm, a higher proportion of responders in the TTF arm had a prior lowgrade histology (36% vs 0%). These differences in treatment responder groups suggest that TTF therapy may differentially benefit certain types of GBM; however, the small numbers of responders in both groups limits generalizations that can be drawn from this analysis.

A second post hoc analysis of the TTF EF-11 pivotal trial data was performed to evaluate OS rates among patients who completed at least 1 complete course of TTF or chemotherapy.<sup>11</sup> These investigators analyzed survival in what they referred to as a “modified ITT [intention-to-treat]” subgroup comprising 93 of 120 (78%) of the original TTF allocated group, versus 117 of 117 (100%) of the original chemotherapy allocated group. This exercise revealed median OS of 7.7 months in the TTF modified ITT (mITT) group compared with 5.9 months in the chemotherapy group (HR=0.69; 95% CI, 0.52 to 0.91;  $p = 0.009$ ). They also showed a trend relationship between proportion of patients with higher TTF compliance and median OS rates ( $p = 0.039$ ). The investigators suggest that TTF provides an OS benefit if used as intended in the FDA-approved label when compared with best chemotherapy. This post hoc analysis is limited as it was not prespecified in the study, includes only 78% of the original TTF allocated patients, and fails to control for noncompliance due to faster clinical deterioration of TTF recipients leading to treatment cessation.

## Noncomparative Studies

A study published in late 2014 included OS data from 457 patients included in the Patient Registry Dataset (PRiDe), a postmarketing registry of all recurrent GBM patients who received NovoTTF therapy in a real-world, clinical practice setting in 91 centers in the United States between October 2011 and November 2013.<sup>12</sup> The median OS rate in the PRiDe clinical practice dataset was reported as significantly superior to that attained in the TTF EF-11 pivotal trial (9.6 months vs 6.6 months; HR=0.66, 95% CI, 0.05 to 0.86;  $p < 0.001$ ). One- and 2-year OS rates for TTF in PRiDe were significantly longer than those in the TTF group in the EF-11 trial (44% vs 20% at 1 year; 30% vs 9% at 2 years, respectively). The PRiDe investigators reported no novel or unexpected treatment-related adverse events compared with the EF-11 trial.

The use of TTF and the corresponding effects on living tissue have been evaluated in uncontrolled studies in a number of clinical settings.<sup>13-15</sup> Kirson et al (2007), for example, reported the findings of a case study examining the effects of TTF therapy delivered by the NovoTTF-100A System in 10 patients with recurrent GBM.<sup>13</sup> Median time to progression (TTP) in these patients was 26.1 weeks, and median OS was 62.2 weeks. The authors noted that these TTP and OS values were more than double the reported medians of historical control patients. No device-related serious adverse events were seen after more than 70 months of cumulative treatment in all of the patients. The only device-related adverse event observed was a mild-to-moderate contact dermatitis beneath the field delivering electrodes. The primary limitation of this study was the use of historical controls, because the patients included may not be comparable on major clinical and prognostic features.<sup>13</sup>

Two small case series have been published of long-term survival (>6 years) with TTF therapy.<sup>16,17</sup> Rulseh et al reported long-term (>7 year) survival in 4 of 20 patients with GBM who were treated with TTF,<sup>16</sup> while Villano et al describe 1 patient with recurrent GBM who was tumor-free more than 6 years after treatment with TTF.<sup>17</sup>

Since the approval of the NovoTTF device, additional case reports and small case series have been reported. Elzinga and Wong reported a case of a patient who demonstrated improved tumor response to bevacizumab in a patient who also received TTF therapy.<sup>18</sup> Another case series ( $n = 3$ ) suggested that adjusting the size of the electric fields may improve response in cases of local tumor progression.<sup>19</sup>

## Ongoing and Unpublished Clinical Trials

Some currently unpublished trials that might influence this review are listed in Table 1.

**Table 1. Summary of Key Trials**

NCT No.	Trial Name	Planned Enrollment Date	Completion
<b>Ongoing</b>			
NCT00916409 <sup>a</sup>	A Prospective, Multi-center Trial of NovoTTF-100A Together with Temozolomide Compared to Temozolomide Alone in Patients with Newly Diagnosed GBM	700	Jul 2016
NCT01894061 <sup>a</sup>	A Prospective Phase II Trial of NovoTTF-100A With Bevacizumab (Avastin) in Patients With Recurrent Glioblastoma	40	Oct 2016
NCT01755624 <sup>a</sup>	A Phase II Randomized Study of TTField Therapy Versus Supportive Care in Non-small Cell Lung Cancer Patients With 1-5 Brain Metastases Following Optimal Standard Local Treatment	60	Jul 2017
NCT01756729 <sup>a</sup>	A Prospective, Non-randomized, Concurrent Control, Open Label, Post-approval Study of NovoTTF-100A in Recurrent GBM Patient	486	Jan 2018
NCT01954576	A Phase II Study of the NovoTTF-100A system, Enhanced by Genomic Analysis to Identify the Genetic Signature of Response in the Treatment of Recurrent Glioblastoma Multiforme	30	May 2018

NCT: national clinical trial. <sup>a</sup> Denotes industry-sponsored or cosponsored trial.

## Summary of Evidence

The evidence for tumor-treatment fields therapy in patients who have recurrent glioblastoma multiforme includes 1 randomized controlled superiority pivotal trial using the U.S. Food and Drug Administration? approved device and a number of small observational studies. Relevant outcomes include overall survival (OS), quality of life (QOL), and treatment-related morbidity. The pivotal trial had numerous methodologic limitations and failed to demonstrate an improvement in OS or disease response. There were some differences reported in QOL, but these data were limited by a low response rate for QOL measures. In addition, the best standard chemotherapy protocols reported in the randomized controlled trial may not reflect current practice, given the increased use of bevacizumab and temozolomide for treatment of patients with recurrent glioblastoma. No data were available to address a comparison to other treatment modalities (eg, radiation, surgery, combination therapy). The evidence is insufficient to determine the effects of the technology on health outcomes.

# Tumor Treating Fields Therapy

## POLICY NUMBER

A.1.01.29

## DESCRIPTION

Glioblastoma multiforme (GBM) is the most common and deadly malignant brain tumor. It has a very poor prognosis and is associated with low quality of life during the course of treatment. Tumor-treatment fields therapy is a new, noninvasive technology intended to treat glioblastoma using alternating electric fields.

### **Glioblastoma Multiforme**

Glioblastomas, also known as glioblastoma multiforme (GBM), are the most common form of malignant primary brain tumor in adults. GBMs are grade IV astrocytomas, a rapidly progressing and deadly type of glial cell tumor that is often resistant to standard medical therapy (eg, bevacizumab, chemotherapy). Together, anaplastic astrocytomas and glioblastomas comprise approximately 38% of all brain and central nervous system tumors. The peak incidence for GBM occurs between the ages of 45 and 70 years, with a median age at diagnosis at 64 years. Glioblastomas have the lowest survival rate of any central nervous system tumor; in one report, about a third of patients survived to 1 year, and the 5-year survival rate was around 5%.

### **Clinical Context and Therapy Purpose**

The purpose of alternating electrical field therapy, more commonly known as tumor treating fields (TTF) therapy, is to provide a treatment option that is better than existing therapies for GBM. TTF has been investigated as an adjunct to temozolomide for the treatment of newly diagnosed GBM and as an alternative or adjunct to medical therapy for progressive or recurrent GBM.

### **Treatment of Newly Diagnosed GBM**

The primary treatment for patients newly diagnosed with GBM is to resect the tumor to confirm a diagnosis while debulking the tumor to relieve symptoms of increased intracranial pressure or compression. If total resection is not feasible, subtotal resection and open biopsy are options. During surgery, some patients may undergo implantation of the tumor cavity with a carmustine (bischloroethylnitrosourea) impregnated wafer. Due to the poor efficacy of local treatment, postsurgical treatment with adjuvant radiotherapy, chemotherapy (typically temozolomide), or a combination of these two therapies is recommended. After adjuvant therapy, patients may undergo maintenance therapy with temozolomide. Maintenance temozolomide is given for 5 days of every 28-day cycle for 6 cycles. Response and overall survival rates with temozolomide are higher in patients who have O<sup>6</sup>-

methylguanine-DNA methyltransferase (*MGMT*) gene promoter methylation (see [Analysis of MGMT Promoter Methylation in Malignant Gliomas \(https://www.bcbsms.com/medical-policy-search#/policy-detail?id=6a48bedf-61a9-4770-98a0-974038e85619\)](https://www.bcbsms.com/medical-policy-search#/policy-detail?id=6a48bedf-61a9-4770-98a0-974038e85619) medical policy).

Prognostic factors for success of therapy are age, histology, performance status or physical condition of the patient, and extent of resection. National Comprehensive Cancer Network recommendations include patient age and Karnofsky Performance Status score as important determinants of postsurgical treatment choice. For patients with good performance status, the most aggressive treatment (standard radiotherapy [RT] plus temozolomide) is recommended. For patients with poor performance status, only single treatment cycles or even palliative or supportive care are recommended. Hypofractionated RT is indicated for patients with poor performance status because it is better tolerated, and more patients are able to complete RT.

Treatment of GBM is rarely curative, and tumors will recur essentially in all patients.

### **Treatment of Recurrent GBM**

When disease recurs, additional debulking surgery may be used if the recurrence is localized. Due to radiation tolerances, re-radiation options for patients with recurrent GBM who have previously received initial external-beam radiotherapy are limited. There is no standard adjunctive treatment for recurrent GBM. Treatment options for recurrent disease include various forms of systemic

medications such as the antivasculature endothelial growth factor drug bevacizumab, alkylating agents such as nitrosoureas (eg, lomustine, carmustine), or retreatment with temozolomide. Medical therapy is associated with side effects that include hematologic toxicity, headache, loss of appetite, nausea, vomiting, and fatigue. Response rates in recurrent disease are less than 10%, and the progression-free survival rate at 6 months is less than 20%. There is a need for new treatments that can improve survival in patients with recurrent GBM or reduce the side effects of treatment while retaining survival benefits.

The questions addressed in this policy are:

- Does TTF, when used as an adjunct to maintenance medical therapy in patients with newly diagnosed GBM, improve the net health outcome?
- Does TTF, when used as an adjunct to medical therapy in patients with recurrent GBM, improve the net health outcome?
- Does TTF, when used as an alternative to medical therapy in patients with recurrent GBM, improve the net health outcome?

The following PICOTS were used to select literature for this policy.

### **Patients**

The relevant populations of interest are patients who have newly diagnosed GBM with good performance status or patients with recurrent GBM with good performance status. Newly diagnosed patients would have undergone initial treatment with surgery, RT, and chemotherapy and be receiving maintenance chemotherapy.

### **Interventions**

Tumor-treatment fields (TTF) therapy is a noninvasive technology intended to treat GBM on an outpatient basis and at home using electrical fields. TTF therapy exposes rapidly dividing cancer cells to electric fields of low intensity and intermediate frequency (200 kHz) that alternate in perpendicular orientation. Tumor-treatment fields therapy is proposed to inhibit tumor growth by two mechanisms: the arrest of cell proliferation by causing microtubule misalignment in the mitotic spindle of rapidly dividing tumor cells and apoptosis due to movement of macromolecules and organelles during telophase. Preclinical studies have indicated that the electric fields may also make the cells more susceptible to chemotherapy.

Optune, formerly NovoTTF-100A System, is the only legally marketed TTF delivery system available in the United States. The portable, battery-powered device is carried in a backpack or shoulder pack while carrying out activities of daily living. For the treatment of glioblastoma, 4 disposable transducer arrays with insulated electrodes are applied to the patient's shaved head. The transducer array layout is typically determined using specialized software. The patient's scalp is re-shaved and the transducer arrays replaced twice a week by the patient, caregiver, or device technician. The device is worn for up to 24 hours a day for the duration of treatment, except for brief periods for personal hygiene and 2 to 3 days at the end of each month. The minimum daily treatment is 18 hours. The minimum duration of treatment is 1 month, with the continuation of treatment available until recurrence.

### **Comparators**

The following practice is currently being used to make decisions about newly diagnosed GBM: maintenance chemotherapy with temozolomide alone.

The following practices are currently being used to make decisions about recurrent GBM: medical therapy.

TTF therapy might also be compared with palliative or supportive care, where survival rarely exceeds 3 to 5 months.

### **Outcomes**

The general outcomes of interest are whether TTF improves survival or quality of life during treatment and, because most GBMs recur, the time to tumor recurrence. Measures of cognitive status and quality of life measures are also of interest to determine whether TTF alters the decline in cognition and quality of life that occur with GBM. Also, adverse events of treatment such as side effects of chemotherapy and the possibility of seizures need to be assessed.

### **Timing**

Due to the rapid progression of GBM, the time of interest for both progression-free survival and overall survival is months.

**Setting**

The setting is outpatient care by an oncologist or neuro-oncologist.

In April 2011, the NovoTTF-100A™ System (Novocure; assigned the generic name of tumor-treatment fields) was approved by the U.S. Food and Drug Administration (FDA) through the premarket approval process. The FDA-approved label reads as follows: "The NovoTTF-100A System is intended as a treatment for adult patients (22 years of age or older) with confirmed GBM [glioblastoma multiforme], following confirmed recurrence in an upper region of the brain (supratentorial) after receiving chemotherapy. The device is intended to be used as a stand-alone treatment, and is intended as an alternative to standard medical therapy for recurrent GBM after surgical and radiation options have been exhausted."

In September 2014, FDA approved Novocure's request to change its products name from NovoTTF-110A System to Optune®.

In October 2015, FDA expanded the indication for Optune® in combination with temozolomide to include newly diagnosed GBM. The device was granted priority review status in May 2015 because there was no legally marketed alternative device currently available for the treatment of newly diagnosed GBM that represents a life-threatening condition. In July 2016, a smaller, lighter version of the Optune® device, called the Optune® System (NovoTTF-200A System), received FDA approval.

The FDA-approved label for newly diagnosed GBM reads as follows: "This device is indicated as treatment for adult patients (22 years of age or older) with histologically-confirmed glioblastoma multiforme (GBM). Optune™ with temozolomide is indicated for the treatment of adult patients with newly diagnosed, supratentorial glioblastoma following maximal debulking surgery and completion of radiation therapy together with concomitant standard of care chemotherapy."

## POLICY

Tumor treating fields therapy to treat glioblastoma multiforme is considered **medically necessary** as an adjunct to standard maintenance therapy with temozolomide in patients with newly diagnosed glioblastoma multiforme following initial treatment with surgery, radiotherapy, and/or chemotherapy under the following conditions:

- Adult patients ≥18 years of age
- Supratentorial tumor
- Karnofsky Performance Status score ≥70%
- Patient understands device use, including the requirement for a shaved head, and is willing to comply with use criteria according to the Food and Drug Administration label (see Policy Guidelines).

Tumor treating fields therapy is considered **investigational** in all other conditions, including but not limited to the following situations:

- As an adjunct to standard medical therapy (eg, bevacizumab, chemotherapy) for patients with progressive or recurrent glioblastoma multiforme
- As an alternative to standard medical therapy for patients with progressive or recurrent glioblastoma multiforme
- For brain metastases
- For cancer in areas other than the brain.

## POLICY EXCEPTIONS

Federal Employee Program (FEP) may dictate that all FDA-approved devices, drugs or biologics may not be considered investigational and thus these devices may be assessed only on the basis of their medical necessity.

## POLICY GUIDELINES

The coverage guidelines outlined in the Medical Policy Manual should not be used in lieu of the Member's specific benefit plan language.

Progression was defined in the EF-14 trial (Stupp et al [2015, 2017]) according to the MacDonald criteria (tumor growth >25% compared with the smallest tumor area measured in the patient during the trial or appearance of one or more new tumors in the brain that are diagnosed radiologically as glioblastoma multiforme).

The Food and Drug Administration label includes the following notices:

- Patients should use Optune for at least 18 hours a day to get the best response to treatment
- Patients should finish at least 4 full weeks of therapy to get the best response to treatment. Stopping treatment before 4 weeks lowers the chances of a response to treatment.

Investigative is defined as the use of any treatment procedure, facility, equipment, drug, device, or supply not yet recognized as a generally accepted standard of good medical practice for the treatment of the condition being treated and; therefore, is not considered medically necessary. For the definition of Investigative, "generally accepted standards of medical practice" means standards that are based on credible scientific evidence published in peer-reviewed medical literature generally recognized by the relevant medical community, and physician specialty society recommendations, and the views of medical practitioners practicing in relevant clinical areas and any other relevant factors. In order for equipment, devices, drugs or supplies [i.e, technologies], to be considered not investigative, the technology must have final approval from the appropriate governmental bodies, and scientific evidence must permit conclusions concerning the effect of the technology on health outcomes, and the technology must improve the net health outcome, and the technology must be as beneficial as any established alternative and the improvement must be attainable outside the testing/investigational setting.

## POLICY HISTORY

04/01/2014: Approved by Medical Policy Advisory Committee.

09/30/2014: Policy reviewed; no changes.

07/23/2015: Code Reference section updated for ICD-10.

11/03/2015: Policy description updated regarding devices. Policy statement unchanged. Investigative definition updated in policy guidelines section.

01/06/2016: Code Reference section updated to add HCPCS codes A4555 and E0766 with an effective date of 01/01/2016.

05/31/2016: Policy number A.1.01.29 added.

09/22/2016: Policy description updated to add section headings. Policy statement revised for clarity; intent unchanged.

08/04/2017: Policy description updated regarding treatment for patients with glioblastoma multiforme and devices. Policy statement updated to state that tumor-treatment fields therapy to treat glioblastoma multiforme (GBM) is investigational as an alternative to standard chemotherapy for patients with progressive or recurrent GBM after initial or repeat treatment with surgery, radiotherapy, and/or chemotherapy and as an adjunct to standard maintenance therapy in patients with newly diagnosed GBM following initial treatment with surgery, radiotherapy, and/or chemotherapy.

09/15/2018: Policy title changed from "Tumor-Treatment Fields Therapy for Glioblastoma" to "Tumor Treating Fields Therapy." Policy description updated regarding treatment of newly diagnosed glioblastoma multiforme (GBM) and recurrent GBM. Added the following policy statement: Tumor treating fields therapy to treat glioblastoma multiforme is considered medically necessary as an adjunct to standard maintenance therapy with temozolomide in patients with newly diagnosed glioblastoma multiforme following initial treatment with surgery, radiotherapy, and/or chemotherapy under certain conditions. Investigational statement updated to state that tumor treating fields therapy is considered investigational in all other conditions. Policy Guidelines updated to define progression. Code Reference section updated to change codes from investigational to medically necessary and add ICD-10 diagnosis codes C71.0 - C71.9.

## SOURCE(S)

## CODE REFERENCE

This may not be a comprehensive list of procedure codes applicable to this policy.

The code(s) listed below are **ONLY** medically necessary if the procedure is performed according to the "Policy" section of this document.

### Medically Necessary Codes

Code Number	Description
<b>CPT-4</b>	
<b>HCPCS</b>	
A4555	Electrode/transducer for use with electrical stimulation device used for cancer treatment, replacement only
A9900	Miscellaneous DME supply, accessory, and/or service component of another HCPCS code
E0766	Electrical stimulation device used for cancer treatment, includes all accessories, any type
E1399	Durable medical equipment, miscellaneous
<b>ICD-10 Procedure</b>	
<b>ICD-10 Diagnosis</b>	
C71.0 - C71.9	Malignant neoplasm of brain

# Tumor Treating Fields Therapy

## POLICY NUMBER

A.1.01.29

## DESCRIPTION

Glioblastoma multiforme (GBM) is the most common and deadly malignant brain tumor. It has a very poor prognosis and is associated with low quality of life during the course of treatment. Tumor-treatment fields therapy is a new, noninvasive technology intended to treat glioblastoma using alternating electric fields.

### **Glioblastoma Multiforme**

Glioblastomas, also known as glioblastoma multiforme (GBM), are the most common form of malignant primary brain tumor in adults. GBMs are grade IV astrocytomas, a rapidly progressing and deadly type of glial cell tumor that is often resistant to standard medical therapy (eg, bevacizumab, chemotherapy). Together, anaplastic astrocytomas and glioblastomas comprise approximately 38% of all brain and central nervous system tumors. The peak incidence for GBM occurs between the ages of 45 and 70 years, with a median age at diagnosis at 64 years. Glioblastomas have the lowest survival rate of any central nervous system tumor; in one report, about a third of patients survived to 1 year, and the 5-year survival rate was around 5%.

### **Clinical Context and Therapy Purpose**

The purpose of alternating electrical field therapy, more commonly known as tumor treating fields (TTF) therapy, is to provide a treatment option that is better than existing therapies for GBM. TTF has been investigated as an adjunct to temozolomide for the treatment of newly diagnosed GBM and as an alternative or adjunct to medical therapy for progressive or recurrent GBM.

### **Treatment of Newly Diagnosed GBM**

The primary treatment for patients newly diagnosed with GBM is to resect the tumor to confirm a diagnosis while debulking the tumor to relieve symptoms of increased intracranial pressure or compression. If total resection is not feasible, subtotal resection and open biopsy are options. During surgery, some patients may undergo implantation of the tumor cavity with a carmustine (bischloroethylnitrosourea) impregnated wafer. Due to the poor efficacy of local treatment, postsurgical treatment with adjuvant radiotherapy, chemotherapy (typically temozolomide), or a combination of these two therapies is recommended. After adjuvant therapy, patients may undergo maintenance therapy with temozolomide. Maintenance temozolomide is given for 5 days of every 28-day cycle for 6 cycles. Response and overall survival rates with temozolomide are higher in patients who have O<sup>6</sup>-methylguanine-DNA methyltransferase (*MGMT*) gene promoter methylation (see [Analysis of MGMT Promoter Methylation in Malignant Gliomas \(https://www.bcbsms.com/medical-policy-search#/policy-detail?id=6a48bedf-61a9-4770-98a0-974038e85619\)](https://www.bcbsms.com/medical-policy-search#/policy-detail?id=6a48bedf-61a9-4770-98a0-974038e85619) medical policy).

Prognostic factors for success of therapy are age, histology, performance status or physical condition of the patient, and extent of resection. National Comprehensive Cancer Network recommendations include patient age and Karnofsky Performance Status score as important determinants of postsurgical treatment choice. For patients with good performance status, the most aggressive treatment (standard radiotherapy [RT] plus temozolomide) is recommended. For patients with poor performance status, only single treatment cycles or even palliative or supportive care are recommended. Hypofractionated RT is indicated for patients with poor performance status because it is better tolerated, and more patients are able to complete RT.

Treatment of GBM is rarely curative, and tumors will recur essentially in all patients.

### **Treatment of Recurrent GBM**

When disease recurs, additional debulking surgery may be used if the recurrence is localized. Due to radiation tolerances, re-radiation options for patients with recurrent GBM who have previously received initial external-beam radiotherapy are limited. There is no standard adjunctive treatment

for recurrent GBM. Treatment options for recurrent disease include various forms of systemic medications such as the antivascular endothelial growth factor drug bevacizumab, alkylating agents such as nitrosoureas (eg, lomustine, carmustine), or retreatment with temozolomide. Medical therapy is associated with side effects that include hematologic toxicity, headache, loss of appetite, nausea, vomiting, and fatigue. Response rates in recurrent disease are less than 10%, and the progression-free survival rate at 6 months is less than 20%. There is a need for new treatments that can improve survival in patients with recurrent GBM or reduce the side effects of treatment while retaining survival benefits.

The questions addressed in this policy are:

- Does TTF, when used as an adjunct to maintenance medical therapy in patients with newly diagnosed GBM, improve the net health outcome?
- Does TTF, when used as an adjunct to medical therapy in patients with recurrent GBM, improve the net health outcome?
- Does TTF, when used as an alternative to medical therapy in patients with recurrent GBM, improve the net health outcome?

The following PICOTS were used to select literature for this policy.

### **Patients**

The relevant populations of interest are patients who have newly diagnosed GBM with good performance status or patients with recurrent GBM with good performance status. Newly diagnosed patients would have undergone initial treatment with surgery, RT, and chemotherapy and be receiving maintenance chemotherapy.

### **Interventions**

Tumor-treatment fields (TTF) therapy is a noninvasive technology intended to treat GBM on an outpatient basis and at home using electrical fields. TTF therapy exposes rapidly dividing cancer cells to electric fields of low intensity and intermediate frequency (200 kHz) that alternate in perpendicular orientation. Tumor-treatment fields therapy is proposed to inhibit tumor growth by two mechanisms: the arrest of cell proliferation by causing microtubule misalignment in the mitotic spindle of rapidly dividing tumor cells and apoptosis due to movement of macromolecules and organelles during telophase. Preclinical studies have indicated that the electric fields may also make the cells more susceptible to chemotherapy.

Optune, formerly NovoTTF-100A System, is the only legally marketed TTF delivery system available in the United States. The portable, battery-powered device is carried in a backpack or shoulder pack while carrying out activities of daily living. For the treatment of glioblastoma, 4 disposable transducer arrays with insulated electrodes are applied to the patient's shaved head. The transducer array layout is typically determined using specialized software. The patient's scalp is re-shaved and the transducer arrays replaced twice a week by the patient, caregiver, or device technician. The device is worn for up to 24 hours a day for the duration of treatment, except for brief periods for personal hygiene and 2 to 3 days at the end of each month. The minimum daily treatment is 18 hours. The minimum duration of treatment is 1 month, with the continuation of treatment available until recurrence.

### **Comparators**

The following practice is currently being used to make decisions about newly diagnosed GBM: maintenance chemotherapy with temozolomide alone.

The following practices are currently being used to make decisions about recurrent GBM: medical therapy.

TTF therapy might also be compared with palliative or supportive care, where survival rarely exceeds 3 to 5 months.

### **Outcomes**

The general outcomes of interest are whether TTF improves survival or quality of life during treatment and, because most GBMs recur, the time to tumor recurrence. Measures of cognitive status and quality of life measures are also of interest to determine whether TTF alters the decline in cognition and quality of life that occur with GBM. Also, adverse events of treatment such as side effects of chemotherapy and the possibility of seizures need to be assessed.

### **Timing**

Due to the rapid progression of GBM, the time of interest for both progression-free survival and overall survival is months.

**Setting**

The setting is outpatient care by an oncologist or neuro-oncologist.

In April 2011, the NovoTTF-100A™ System (Novocure; assigned the generic name of tumor-treatment fields) was approved by the U.S. Food and Drug Administration (FDA) through the premarket approval process. The FDA-approved label reads as follows: "The NovoTTF-100A System is intended as a treatment for adult patients (22 years of age or older) with confirmed GBM [glioblastoma multiforme], following confirmed recurrence in an upper region of the brain (supratentorial) after receiving chemotherapy. The device is intended to be used as a stand-alone treatment, and is intended as an alternative to standard medical therapy for recurrent GBM after surgical and radiation options have been exhausted."

In September 2014, FDA approved Novocure's request to change its products name from NovoTTF-110A System to Optune®.

In October 2015, FDA expanded the indication for Optune® in combination with temozolomide to include newly diagnosed GBM. The device was granted priority review status in May 2015 because there was no legally marketed alternative device currently available for the treatment of newly diagnosed GBM that represents a life-threatening condition. In July 2016, a smaller, lighter version of the Optune® device, called the Optune® System (NovoTTF-200A System), received FDA approval.

The FDA-approved label for newly diagnosed GBM reads as follows: "This device is indicated as treatment for adult patients (22 years of age or older) with histologically-confirmed glioblastoma multiforme (GBM). Optune™ with temozolomide is indicated for the treatment of adult patients with newly diagnosed, supratentorial glioblastoma following maximal debulking surgery and completion of radiation therapy together with concomitant standard of care chemotherapy."

## POLICY

Tumor treating fields therapy to treat glioblastoma multiforme is considered **medically necessary** as an adjunct to standard maintenance therapy with temozolomide in patients with newly diagnosed glioblastoma multiforme following initial treatment with surgery, radiotherapy, and/or chemotherapy under the following conditions:

- Adult patients ≥18 years of age
- Supratentorial tumor
- Karnofsky Performance Status score ≥70%
- Patient understands device use, including the requirement for a shaved head, and is willing to comply with use criteria according to the Food and Drug Administration label (see Policy Guidelines).

Tumor treating fields therapy is considered **investigational** in all other conditions, including but not limited to the following situations:

- As an adjunct to standard medical therapy (eg, bevacizumab, chemotherapy) for patients with progressive or recurrent glioblastoma multiforme
- As an alternative to standard medical therapy for patients with progressive or recurrent glioblastoma multiforme
- For brain metastases
- For cancer in areas other than the brain.

## POLICY EXCEPTIONS

Federal Employee Program (FEP) may dictate that all FDA-approved devices, drugs or biologics may not be considered investigational and thus these devices may be assessed only on the basis of their medical necessity.

## POLICY GUIDELINES

The coverage guidelines outlined in the Medical Policy Manual should not be used in lieu of the Member's specific benefit plan language.

Progression was defined in the EF-14 trial (Stupp et al [2015, 2017]) according to the MacDonald criteria (tumor growth >25% compared with the smallest tumor area measured in the patient during the trial or appearance of one or more new tumors in the brain that are diagnosed radiologically as glioblastoma multiforme).

The Food and Drug Administration label includes the following notices:

- Patients should use Optune for at least 18 hours a day to get the best response to treatment
- Patients should finish at least 4 full weeks of therapy to get the best response to treatment. Stopping treatment before 4 weeks lowers the chances of a response to treatment.

Investigative is defined as the use of any treatment procedure, facility, equipment, drug, device, or supply not yet recognized as a generally accepted standard of good medical practice for the treatment of the condition being treated and; therefore, is not considered medically necessary. For the definition of Investigative, "generally accepted standards of medical practice" means standards that are based on credible scientific evidence published in peer-reviewed medical literature generally recognized by the relevant medical community, and physician specialty society recommendations, and the views of medical practitioners practicing in relevant clinical areas and any other relevant factors. In order for equipment, devices, drugs or supplies [i.e, technologies], to be considered not investigative, the technology must have final approval from the appropriate governmental bodies, and scientific evidence must permit conclusions concerning the effect of the technology on health outcomes, and the technology must improve the net health outcome, and the technology must be as beneficial as any established alternative and the improvement must be attainable outside the testing/investigational setting.

## POLICY HISTORY

04/01/2014: Approved by Medical Policy Advisory Committee.

09/30/2014: Policy reviewed; no changes.

07/23/2015: Code Reference section updated for ICD-10.

11/03/2015: Policy description updated regarding devices. Policy statement unchanged. Investigative definition updated in policy guidelines section.

01/06/2016: Code Reference section updated to add HCPCS codes A4555 and E0766 with an effective date of 01/01/2016.

05/31/2016: Policy number A.1.01.29 added.

09/22/2016: Policy description updated to add section headings. Policy statement revised for clarity; intent unchanged.

08/04/2017: Policy description updated regarding treatment for patients with glioblastoma multiforme and devices. Policy statement updated to state that tumor-treatment fields therapy to treat glioblastoma multiforme (GBM) is investigational as an alternative to standard chemotherapy for patients with progressive or recurrent GBM after initial or repeat treatment with surgery, radiotherapy, and/or chemotherapy and as an adjunct to standard maintenance therapy in patients with newly diagnosed GBM following initial treatment with surgery, radiotherapy, and/or chemotherapy.

09/15/2018: Policy title changed from "Tumor-Treatment Fields Therapy for Glioblastoma" to "Tumor Treating Fields Therapy." Policy description updated regarding treatment of newly diagnosed glioblastoma multiforme (GBM) and recurrent GBM. Added the following policy statement: Tumor treating fields therapy to treat glioblastoma multiforme is considered medically necessary as an adjunct to standard maintenance therapy with temozolomide in patients with newly diagnosed glioblastoma multiforme following initial treatment with surgery, radiotherapy, and/or chemotherapy under certain conditions. Investigational statement updated to state that tumor treating fields therapy is considered investigational in all other conditions. Policy Guidelines updated to define progression. Code Reference section updated to change codes from investigational to medically necessary and add ICD-10 diagnosis codes C71.0 - C71.9.

## SOURCE(S)

Blue Cross and Blue Shield Association Policy #1.01.29

## CODE REFERENCE

**This may not be a comprehensive list of procedure codes applicable to this policy.**

**The code(s) listed below are ONLY medically necessary if the procedure is performed according to the "Policy" section of this document.**

# Tumor-Treatment Fields Therapy

**Policy Number:** 1.01.29

**Last Review:** 9/2018

**Origination:** 12/2013

**Next Review:** 12/2018

## **Policy**

Blue Cross and Blue Shield of Kansas City (Blue KC) will provide coverage for Tumor Treating Fields Therapy when it is determined to be medically necessary because the criteria shown below are met.

Please note that this is a type of electrical stimulation that is considered a benefit exclusion in many health plan contracts.

## **When Policy Topic is covered**

Tumor treating fields therapy to treat glioblastoma multiforme is considered **medically necessary** as an adjunct to standard maintenance therapy with temozolomide in patients with newly diagnosed glioblastoma multiforme following initial treatment with surgery, radiotherapy, and/or chemotherapy under the following conditions:

- Adult patients  $\geq 18$  years of age
- Supratentorial tumor
- Karnofsky Performance Status score  $\geq 70\%$
- Patient understands device use, including the requirement for a shaved head, and is willing to comply with use criteria according to the Food and Drug Administration label (Considerations).

## **When Policy Topic is not covered**

Tumor treatment fields therapy to treat glioblastoma is considered **investigational**, including but not limited to the following situations:

- As an adjunct to standard medical therapy (eg, bevacizumab, chemotherapy) for patients with progressive or recurrent glioblastoma multiforme
- As an alternative to standard medical therapy for patients with progressive or recurrent glioblastoma multiforme
- For brain metastases
- For cancer in areas other than the brain.

## **Considerations**

Progression was defined in the EF-14 trial (Stupp et al [2015, 2017]) according to the MacDonald criteria (tumor growth  $>25\%$  compared with the smallest tumor

area measured in the patient during the trial or appearance of 1 or more new tumors in the brain that are diagnosed radiologically as glioblastoma multiforme).

The Food and Drug Administration label includes the following notices:

- Patients should use Optune for at least 18 hours a day to get the best response to treatment
- Patients should finish at least 4 full weeks of therapy to get the best response to treatment. Stopping treatment before 4 weeks lowers the chances of a response to treatment.

There are no specific codes for the initial application of this system or instruction on use. The patient reapplies the transducer arrays at home after the initial instruction.

There are HCPCS codes for the system and the transducer arrays:

E0766 Electrical stimulation device, used for cancer treatment, includes all accessories, any type

A4555 Electrode/transducer for use with electrical stimulation device, used for cancer treatment, replacement only.

Individuals: <ul style="list-style-type: none"> <li>• With progressive or recurrent glioblastoma multiforme</li> </ul>	Interventions of interest are: <ul style="list-style-type: none"> <li>• Tumor treating fields therapy as an adjunct or alternative to medical therapy</li> </ul>	Comparators of interest are: <ul style="list-style-type: none"> <li>• Standard medical therapy</li> </ul>	Relevant outcomes include: <ul style="list-style-type: none"> <li>• Overall survival</li> <li>• Disease-specific survival</li> <li>• Quality of life</li> <li>• Treatment-related morbidity</li> </ul>

Glioblastoma multiforme (GBM) is the most common and deadly malignant brain tumor. It has a very poor prognosis and is associated with low quality of life during of treatment. Tumor treatment fields (TTF) therapy is a new, noninvasive technology intended to treat glioblastoma using alternating electric fields.

For individuals who have newly diagnosed GBM on maintenance therapy after initial treatment who receive TTF therapy as an adjunct to standard maintenance therapy, the evidence includes a randomized controlled trial (RCT). Relevant

outcomes include overall survival, disease-specific survival, symptoms, functional outcomes, quality of life, and treatment-related morbidity. The EF-14 trial found a significant increase of 2.7 months in progression-free survival and an increase of 4.9 months in overall survival with the addition of TTF therapy to standard maintenance therapy (ie, temozolomide) in patients with newly diagnosed GBM. Although patients were not blinded to treatment assignment, progression-free survival was assessed by blinded evaluators, and the placebo effects on the objective measure of overall survival are expected to be minimal. This technology represents a clinically significant option in the treatment of patients with GBM, for whom options are limited. The evidence is sufficient to determine that the technology results in a meaningful improvement in the net health outcome.

For individuals who have progressive or recurrent GBM who receive TTF therapy as an adjunct or alternative to standard medical therapy, the evidence includes an RCT and nonrandomized comparative studies. Relevant outcomes are overall survival, disease-specific survival, quality of life, and treatment-related morbidity. The single RCT evaluating TTF therapy for recurrent GBM did not show superiority of TTF therapy for the primary outcome (overall survival) compared with physicians' choice chemotherapy. Because no serious adverse effects have been identified with TTF therapy, this raises the possibility that treatment with TTF might reduce the toxicity associated with treatment for recurrent GBM. A reduction in chemotherapy-associated toxicity without loss of efficacy would be considered a net health benefit. However, this RCT is not sufficient to permit conclusions on the efficacy of the device. Because the trial was not designed as a noninferiority trial, no inferences of noninferiority compared with chemotherapy can be made. Also, quality of life assessment was measured in an insufficient number of patients to reach firm conclusions on differences in quality of life between TTF therapy and medical treatment. The highest quality study of TTF combined with medical treatment for recurrent GBM is a post hoc analysis of the EF-14 trial. A high-quality, prospective RCT is needed. The evidence is insufficient to determine the effects of the technology on health outcomes.

## **Background**

### **Glioblastoma Multiforme**

Glioblastomas, also known as glioblastoma multiforme (GBM), are the most common form of malignant primary brain tumor in adults.<sup>1</sup> GBMs are grade IV astrocytomas, a rapidly progressing and deadly type of glial cell tumor that is often resistant to standard medical therapy (eg, bevacizumab, chemotherapy). Together, anaplastic astrocytomas and glioblastomas comprise approximately 38% of all brain and central nervous system tumors.<sup>1</sup> The peak incidence for GBM occurs between the ages of 45 and 70 years, with a median age at diagnosis of 64 years. Glioblastomas have the lowest survival rate of any central nervous system tumor; in one report, about a third of patients survived to 1 year, and the 5-year survival rate was around 5%.<sup>2</sup>

### **Clinical Context and Therapy Purpose**

The purpose of alternating electrical field therapy, more commonly known as tumor treating fields (TTF) therapy, is to provide a treatment option that is better

than existing therapies for GBM. TTF has been investigated as an adjunct to temozolomide for the treatment of newly diagnosed GBM and as an alternative or adjunct to medical therapy for progressive or recurrent GBM

### ***Treatment of Newly Diagnosed GBM***

The primary treatment for patients newly diagnosed with GBM is to resect the tumor to confirm a diagnosis while debulking the tumor to relieve symptoms of increased intracranial pressure or compression. If total resection is not feasible, subtotal resection and open biopsy are options. During surgery, some patients may undergo implantation of the tumor cavity with a carmustine (bis-chloroethylnitrosourea) impregnated wafer. Due to the poor efficacy of local treatment, postsurgical treatment with adjuvant radiotherapy, chemotherapy (typically temozolomide), or a combination of these 2 therapies is recommended. After adjuvant therapy, patients may undergo maintenance therapy with temozolomide. Maintenance temozolomide is given for 5 days of every 28-day cycle for 6 cycles. Response and overall survival rates with temozolomide are higher in patients who have O<sup>6</sup>-methylguanine-DNA methyltransferase (*MGMT*) gene promoter methylation (see separate policy).

Prognostic factors for therapy success are age, histology, performance status or physical condition of the patient, and extent of resection. National Comprehensive Cancer Network recommendations include patient age and Karnofsky Performance Status score as important determinants of postsurgical treatment choice (see the Supplemental Information section).<sup>3</sup> For patients with good performance status, the most aggressive treatment (standard radiotherapy [RT] plus temozolomide) is recommended. For patients with poor performance status, only single treatment cycles or even palliative or supportive care are recommended. Hypofractionated RT is indicated for patients with poor performance status because it is better tolerated, and more patients are able to complete RT.

Treatment of GBM is rarely curative, and tumors will recur essentially all patients.

### ***Treatment of Recurrent GBM***

When disease recurs, additional debulking surgery may be used if the recurrence is localized. Due to radiation tolerances, re-radiation options for patients with recurrent GBM who have previously received initial external-beam radiotherapy are limited. There is no standard adjunctive treatment for recurrent GBM. Treatment options for recurrent disease include various forms of systemic medications such as the antivasular endothelial growth factor drug bevacizumab, alkylating agents such as nitrosoureas (eg, lomustine, carmustine), or retreatment with temozolomide. Medical therapy is associated with side effects that include hematologic toxicity, headache, loss of appetite, nausea, vomiting, and fatigue. Response rates in recurrent disease are less than 10%, and the progression-free survival rate at 6 months is less than 20%.<sup>4</sup> There is a need for new treatments that can improve survival in patients with recurrent GBM or reduce the side effects of treatment while retaining survival benefits.

The questions addressed in this evidence review are:

- Does TTF, when used as an adjunct to maintenance medical therapy in patients with newly diagnosed GBM, improve the net health outcome?
- Does TTF, when used as an adjunct to medical therapy in patients with recurrent GBM, improve the net health outcome?
- Does TTF, when used as an alternative to medical therapy in patients with recurrent GBM, improve the net health outcome?

The following PICOTS were used to select literature to inform this review.

### ***Patients***

The relevant populations of interest are patients who have newly diagnosed GBM with good performance status or patients with recurrent GBM with good performance status. Newly diagnosed patients would have undergone initial treatment with surgery, RT, and chemotherapy and be receiving maintenance chemotherapy.

### ***Interventions***

TTF therapy is a noninvasive technology intended to treat GBM on an outpatient basis and at home using electrical fields.<sup>4-6</sup> TTF therapy exposes rapidly dividing cancer cells to electric fields of low intensity and intermediate frequency (200 kHz) that alternate in perpendicular orientation. TTF therapy is proposed to inhibit tumor growth by 2 mechanisms: the arrest of cell proliferation by causing microtubule misalignment in the mitotic spindle of rapidly dividing tumor cells and apoptosis due to movement of macromolecules and organelles during telophase.<sup>5,6</sup> Preclinical studies have indicated that the electric fields may also make the cells more susceptible to chemotherapy.

Optune (formerly NovoTTF-100A System) is the only legally marketed TTF delivery system available in the United States. The portable, battery-powered device is carried in a backpack or shoulder pack while carrying out activities of daily living. For the treatment of glioblastoma, 4 disposable transducer arrays with insulated electrodes are applied to the patient's shaved head. The transducer array layout is typically determined using specialized software. The patient's scalp is re-shaved and the transducer arrays replaced twice a week by the patient, caregiver, or device technician. The device is worn for up to 24 hours a day for the duration of treatment, except for brief periods for personal hygiene and 2 to 3 days at the end of each month. The minimum daily treatment is 18 hours. The minimum duration of treatment is 1 month, with the continuation of treatment available until recurrence.

### ***Comparators***

The following practice is currently being used to make decisions about newly diagnosed GBM: maintenance chemotherapy with temozolomide alone.

The following practices are currently being used to make decisions about recurrent GBM: medical therapy.

TTF therapy might also be compared with palliative or supportive care, where survival rarely exceeds 3 to 5 months.<sup>4</sup>

### **Outcomes**

The general outcomes of interest are whether TTF improves survival or quality of life during treatment and, because most GBMs recur, the time to tumor recurrence. Measures of cognitive status and quality of life measures are also of interest to determine whether TTF alters the decline in cognition and quality of life that occur with GBM. Also, adverse events of treatment such as side effects of chemotherapy and the possibility of seizures need to be assessed.

### **Timing**

Due to the rapid progression of GBM, the time of interest for both progression-free survival and overall survival is months.

### **Setting**

The setting is outpatient care by an oncologist or neuro-oncologist.

### **Regulatory Status**

In April 2011, the NovoTTF-100A™ System (Novocure; assigned the generic name of TTF) was approved by the U.S. Food and Drug Administration (FDA) through the premarket approval process.<sup>7</sup> The FDA-approved label reads as follows: "The NovoTTF-100A System is intended as a treatment for adult patients (22 years of age or older) with confirmed GBM, following confirmed recurrence in an upper region of the brain (supratentorial) after receiving chemotherapy. The device is intended to be used as a stand-alone treatment and is intended as an alternative to standard medical therapy for recurrent GBM after surgical and radiation options have been exhausted."

In September 2014, FDA approved Novocure's request for a product name change from NovoTTF-110A System to Optune®.<sup>8</sup>

In October 2015, FDA expanded the indication for Optune® in combination with temozolomide to include newly diagnosed GBM.<sup>9</sup> The device was granted priority review status in May 2015 because there was no legally marketed alternative device available for the treatment of newly diagnosed GBM, a life-threatening condition. In July 2016, a smaller, lighter version of the Optune® device, called the Optune® System (NovoTTF-200A System), received FDA approval.

The FDA-approved label for newly diagnosed GBM reads as follows: "This device is indicated as treatment for adult patients (22 years of age or older) with histologically-confirmed glioblastoma multiforme (GBM). Optune™ with temozolomide is indicated for the treatment of adult patients with newly diagnosed, supratentorial glioblastoma following maximal debulking surgery and completion of radiation therapy together with concomitant standard of care chemotherapy."

## **Rationale**

---

This evidence review was created in August 2013 and has been updated regularly with searches of the MEDLINE database. The most recent literature update was performed through April 5, 2018.

Evidence reviews assess the clinical evidence to determine whether the use of a technology improves the net health outcome. Broadly defined, health outcomes are length of life, quality of life, and ability to function—including benefits and harms. Every clinical condition has specific outcomes that are important to patients and to managing the course of that condition. Validated outcome measures are necessary to ascertain whether a condition improves or worsens; and whether the magnitude of that change is clinically significant. The net health outcome is a balance of benefits and harms.

To assess whether the evidence is sufficient to draw conclusions about the net health outcome of a technology, 2 domains are examined: the relevance and the quality and credibility. To be relevant, studies must represent one or more intended clinical use of the technology in the intended population and compare an effective and appropriate alternative at a comparable intensity. For some conditions, the alternative will be supportive care or surveillance. The quality and credibility of the evidence depend on study design and conduct, minimizing bias and confounding that can generate incorrect findings. The randomized controlled trial (RCT) is preferred to assess efficacy; however, in some circumstances, nonrandomized studies may be adequate. RCTs are rarely large enough or long enough to capture less common adverse events and long-term effects. Other types of studies can be used for these purposes and to assess generalizability to broader clinical populations and settings of clinical practice.

For this review, 3 indications are evaluated: (1) tumor treating fields (TTF) as an adjunct to maintenance chemotherapy in newly diagnosed patients following initial treatment with surgery, radiotherapy and chemotherapy and (2) TTF as an adjunct or (3) alternative to medical therapy (eg, bevacizumab, chemotherapy) in progressive or recurrent glioblastoma multiforme (GBM).

### **Study Selection**

The PICOTS was used to select relevant studies.

- To assess efficacy outcomes, comparative controlled prospective trials were sought, with a preference for RCTs.
- To assess longer term outcomes and adverse events, single-arm studies that capture longer periods of follow-up and/or larger populations were sought.
- Within each category of study design, studies with larger sample size studies and longer duration were sought.

### **TTF Therapy as an Adjunct to Standard Maintenance Care for Newly Diagnosed GBM**

## Randomized Controlled Trials

Stupp et al (2017) published results of the EF-14 multicenter, open-label phase 3 RCT that evaluated maintenance therapy with TTF for newly diagnosed GBM.<sup>10</sup> The trial included 695 patients from 83 sites who had supratentorial GBM and had completed standard treatment consisting of biopsy or surgical resection followed by radiotherapy and chemotherapy (see Table 1). A Karnofsky Performance Status (KPS) score of 70 or higher was an additional inclusion criterion to ensure independence in activities of daily living, and patients with rapidly progressing GBM following radiochemotherapy were excluded from the trial. Patients were randomized in a 2:1 fashion to TTF plus maintenance temozolomide or maintenance temozolomide alone.

All patients were seen monthly for follow-up. Quality of life (QOL) was assessed every 3 months, and magnetic resonance imaging (MRI) was performed every 2 months until tumor progression. Tumor progression on MRI was adjudicated by a central review committee blinded to treatment group. The primary outcome was progression-free survival (PFS), and the secondary outcome was overall survival (OS). The analysis was by intention-to-treat, including 26 patients from the control arm who crossed over to TTF following the planned interim analysis.

In 2014, an independent data and safety monitoring board concluded from the planned interim analysis that the trial met its predefined boundaries for success (improvement in PFS and OS) and recommended trial termination. The Food and Drug Administration approved the trial termination, and the trial was closed to recruitment with 695 of the planned 700 participants randomized. Control arm participants were allowed to cross over to the experimental treatment at this time. The interim analysis, which the Food and Drug Administration considered for the 2015 expanded approval of Optune, was published by Stupp et al (2015).<sup>11</sup> At the time of the interim analysis, data were available for 210 patients randomized to TTF plus temozolomide and 105 patients to temozolomide alone. Follow-up of the remainder of the 695 enrolled patients continued after enrollment was closed.

**Table 1. Key Randomized Controlled Trial Characteristics for Newly Diagnosed Glioblastoma**

Study; Trial	Countries	Sites	Dates	Participants	Interventions	
					Active	Comparator
<b>Stupp et al (2017)<sup>10</sup>; EF-14</b>	U.S., E.U., South Korea, Israel	83	2009-2016	<ul style="list-style-type: none"> <li>695 newly diagnosed with GBM and treated by radiochemotherapy</li> <li>KPS score <math>\geq 70</math></li> </ul>	TTF >18 h/d plus maintenance temozolomide (n=466)	Maintenance temozolomide alone (5 d every 28 d for 6 cycles) (n=229)

GBM: glioblastoma multiforme; h/d; hours per day; KPS: Karnofsky Performance Status; TTF: tumor treatment fields.

Results of the final analysis of the EF-14 trial were similar to the interim analysis and are shown in Table 2. Both PFS and OS improved with the addition of TTF therapy to standard maintenance chemotherapy (ie, temozolomide). PFS increased

by 2.7 mo ( $p < 0.001$ ) and OS increased by 4.9 mo ( $p < 0.001$ ) in the TTF group. The time to a decrease in mental function was 2.5 months longer with TTF therapy ( $p < 0.01$ ).

There was a similar percentage of dropouts at the final analysis—with 49 (11%) patients in the TTF group and 27 (12%) patients in the temozolomide alone group. More treatment cycles with temozolomide were administered in the TTF group (median, 6 for TTF group vs 5 for controls), a finding that is consistent with the longer PFS. Rates of adverse events were similar between the groups, including rates of seizures. In secondary analysis of patients who had not progressed, there was no reduction in health-related quality of life with TTF compared with temozolomide alone aside from “itchy skin”.<sup>12</sup> Interpretation of this result is limited by the low percentage of patients who completed the health-related quality of life assessments at follow-up (65.8% of the 655 patients alive at 3 months and 41.7% of the 473 patients alive at 12 months). A mixed-model analysis, which accounts for missing data, confirmed the results of the mean change from baseline analysis.

**Table 2. Key Randomized Controlled Trial Results for Newly Diagnosed Glioblastoma**

Study	Final N (%)	Median PFS (95% CI), mo	Median OS (95% CI), mo	Systemic Adverse Events, n (%)	Seizures, n (%)	Time to 6-Point Decline in MMSE Score (95% CI), mo
<b>Stupp et al (2017)<sup>10</sup></b>						
<b>TTF + temozolomide</b>	417 (89)	6.7 (6.1 to 8.1)	20.9 (19.3 to 22.7)	218 (48)	26 (6)	16.7 (14.7 to 19.0)
<b>Temozolomide alone</b>	202 (88)	4.0 (3.8 to 4.4)	16.0 (14.0 to 18.4)	94 (44)	13 (6)	14.2 (12.7 to 17.0)
<b>HR (95% CI)</b>		0.63 (0.52 to 0.76)	0.63 (0.53 to 0.76)			0.79 (0.66 to 0.95)
<b>P value</b>		<0.001	<0.001	0.58		0.01

CI: confidence interval; HR: hazard ratio; MMSE: Mini-Mental State Examination; OS: overall survival; PFS: progression-free survival; TTF: tumor treatment fields.

Tables 3 and 4 display notable gaps identified in this trial, the major limitation is the lack of patient blinding to treatment assignment. However, PFS was assessed by investigators who were blinded to treatment and placebo effects on OS were expected to be minimal. Investigators considered it practically unfeasible (due to the heat and current of the TTF therapy) and ethically unacceptable to submit the control patients to repeated shaving of the head and continuous wear of a sham device over many months.

### Section Summary: TTF Therapy as an Adjunct to Standard Maintenance Care for Newly Diagnosed GBM

The final analysis of the EF-14 trial, which included 695 patients from 83 sites, found a statistically and clinically significant increase of 2.7 months in PFS and an increase of 4.9 months in OS with the addition of TTF therapy to standard maintenance therapy (ie, temozolomide) in patients with newly diagnosed GBM. There was no sham control, and patients were not blinded to treatment assignment, but PFS was assessed by blinded evaluators, and placebo effects on the objective measure of OS were likely to be minimal. There was no evidence of a negative impact of TTF therapy on health-related quality of life, except for itchy skin from the transducers.

## TTF Therapy as an Adjunct or Alternative to Medical Therapy for Progressive or Recurrent GBM

### Randomized Controlled Trials

The 2011 Food and Drug Administration approval of the NovoTTF-100A System (now called Optune) was based on a phase 3 multinational RCT (EF-11), results of which were published by Stupp et al (2012).<sup>4</sup> This trial compared TTF therapy alone with physician's choice medical therapy in 237 adults who had relapsed or progressive glioblastoma (see Table 5). Patients had failed conventional treatment with radiotherapy, chemotherapy, and/or surgery, and more than 80% of participants had failed 2 or more prior chemotherapy regimens. In this trial, the term chemotherapy also applied to targeted agents such as bevacizumab. Patient characteristics and performance of additional post-recurrence debulking surgery were similar in the 2 groups.

**Table 5. Summary of Key Randomized Controlled Trial Characteristics for Progressive or Recurrent Glioblastoma**

Study; Trial	Countries	Sites	Dates	Participants	Interventions	
					Active	Comparator
<b>Stupp et al (2012)<sup>4</sup>; EF-11</b>	U.S., E.U., Israel	28	1987-2013	<ul style="list-style-type: none"> <li>237 adults with relapsed or progressive supratentorial glioblastoma</li> <li>KPS score <math>\geq 70\%</math></li> </ul>	120 patients treated with TTF alone, 93 (78%) completed 1 cycle	117 patients treated with physician's choice of medical therapy <sup>a</sup>

EU: European Union; KPS: Karnofsky Performance Status; TTF: tumor treating fields.

<sup>a</sup> Medical therapy included bevacizumab, irinotecan, nitrosoureas, platinum-based chemotherapy (ie, carboplatin); temozolomide; or a combination of procarbazine, chloroethyl ether, and vincristine.

Participants were followed monthly, including laboratory tests. MRI images were evaluated at 2, 4, and 6 months from initiation of treatment, with subsequent MRIs performed according to local practice until disease progression. QOL questionnaires were completed every 3 months. Medical follow-up continued for 2 months after disease progression. Monthly telephone interviews with participants' caregivers were used to assess mortality rates. The primary end point was OS. Secondary end points included PFS, the percentage of patients with PFS at 6 months, time to progression, 1-year survival rate, QOL, and radiologic response. All end points were evaluated using intention-to-treat analysis.

The trial did not reach its primary end point of improved survival compared with active medical therapy (see Table 6). With a median follow-up of 39 months, 93% of patients had died. There was not a statistically significant difference in survival rates at 1, 2, and 3 years between groups. Patients in the TTF group did not, however, suffer the typical systemic side effects of chemotherapy. The most common adverse event in the TTF group was grade 1 and 2 contact dermatitis on the scalp, which resolved with topical corticosteroids and did not require treatment breaks. Control participants experienced grade 2, 3, or 4 events by organ system

related to the pharmacologic activity of chemotherapy agents used. Hematologic events of grade 2 or greater were observed in 17% of chemotherapy patients compared with 3% of TTF patients. Gastrointestinal disorders of grade 2 or greater were identified in 17% of chemotherapy patients compared with 4% of TTF patients. Severe (grades 3-4) hematologic and gastrointestinal toxicity was observed in 7% of chemotherapy controls compared with 1% of the TTF group.

Longitudinal QOL data, available in 63 (27%) participants, showed no meaningful differences between groups for the domains of global health and social functioning. However, cognitive and emotional functioning domains favored TTF therapy. Symptom scale analysis was by treatment-associated toxicity; appetite loss, diarrhea, constipation, nausea, and vomiting were directly related to the chemotherapy administration.

The trial had a number of limitations (see Tables 7 and 8), that included lack of blinding and high loss to follow-up. Discontinuation of TTF therapy occurred in 22% of patients due to noncompliance or inability to handle the device, usually within the first few days. In the control group, 21 (18%) patients did not return to the treatment site, and details on disease progression and toxicity were not available. Longitudinal QOL could be analyzed only for 27% of patients who remained on study therapy for 3 months. The trial was designed as a superiority trial and did not provide adequate evidence of noninferiority.

## Nonrandomized Comparative Studies

Kesari et al (2017) conducted a post hoc analysis of the EF-14 trial (see Stupp et al [2017] above) to evaluate the efficacy of TTF in patients who had the first recurrence.<sup>13</sup> Some patients in the temozolomide alone group crossed over to receive TTF plus chemotherapy after the first recurrence, resulting in 144 patients who received TTF fields plus chemotherapy and 60 patients who received chemotherapy alone for recurrent GBM (see Table 9). Patient characteristics and second-line treatments were well-balanced between the groups, with bevacizumab the most common second-line therapy. The median OS in patients treated with systemic therapy alone was 9.2 months (see Table 10). In comparison, the group

of patients who received TTF therapy in addition to systemic therapy had a median OS of 11.8 months ( $p=0.043$ ).

A registry study published Mrugala et al (2014) assessed OS data from patients who received NovoTTF therapy in a real-world, clinical practice setting (see Table 9).<sup>14</sup> Concurrent treatment was not captured in the registry, and it is possible that some patients received combination therapy. Median OS in the PRiDe clinical practice dataset (9.6 mo) was reported as superior to that attained in the EF-11 pivotal trial (6.6 mo,  $p<0.001$ ) (see Table 10). More patients in the PRiDe registry were treated for first recurrence (33% vs 9%), and more had received bevacizumab as prior therapy (55% vs 19%). The PRiDe investigators reported no novel or unexpected treatment-related adverse events compared with the EF-11 trial.

<b>P value</b>	<0.001		

CI: confidence interval; OS: overall survival, TTF: tumor treating fields.

Post hoc analyses of the EF-11 pivotal trial have been reported. Wong et al (2014) published a subgroup analysis to determine characteristics of responders and nonresponders in the active treatment and active treatment control.<sup>15</sup> They found

that responders had a lower grade of histology and lower daily dexamethasone use than nonresponders. A second post hoc analysis by Kanner et al (2014) of the EF-11 pivotal trial data was performed to evaluate OS among patients who finished at least 1 complete course of TTF or chemotherapy.<sup>16</sup> The investigators reported that median OS was 7.7 months in the TTF group compared with 5.9 months in the chemotherapy group ( $p=0.009$ ). These post hoc analyses are considered to be hypothesis-generating.

### **Section Summary: TTF Therapy as an Adjunct or Alternative to Chemotherapy for Progressive or Recurrent GBM**

The single RCT for TTF as an alternative to chemotherapy reported that outcomes following TTF therapy were similar to outcomes following standard chemotherapy. However, this RCT is not sufficient to permit conclusions on the efficacy of the device. The noninferiority of TTF compared with chemotherapy might be considered a sufficient health benefit, if TTF reduced treatment toxicity. However, because the trial was not designed as a noninferiority trial no inferences of noninferiority compared with chemotherapy can be made. Physician's choice therapy during the trial was heterogenous, although analysis indicated that survival was not affected by choice of chemotherapy. More patients in the TTF group than in the control group did not complete the treatment course. The number of patients who contributed QOL data was approximately one-quarter of total enrollment, and the self-reported QOL indicators might have been subject to bias due to the lack of blinding.

A nonrandomized post hoc evaluation of the EF-14 trial suggests that TTF may improve survival when combined with chemotherapy for recurrent GBM. This analysis should be considered hypothesis-generating, and further study in high-quality RCTs is needed.

### **Summary of Evidence**

For individuals who have newly diagnosed GBM on maintenance therapy after initial treatment who receive TTF therapy as an adjunct to standard maintenance therapy, the evidence includes an RCT. Relevant outcomes include overall survival, disease-specific survival, symptoms, functional outcomes, quality of life, and treatment-related morbidity. The EF-14 trial found a significant increase of 2.7 months in progression-free survival and an increase of 4.9 months in overall survival with the addition of TTF therapy to standard maintenance therapy (ie, temozolomide) in patients with newly diagnosed GBM. Although patients were not blinded to treatment assignment, progression-free survival was assessed by blinded evaluators, and the placebo effects on the objective measure of overall survival are expected to be minimal. This technology represents a clinically significant option in the treatment of patients with GBM, for whom options are limited. The evidence is sufficient to determine that the technology results in a meaningful improvement in the net health outcome.

For individuals who have progressive or recurrent GBM who receive TTF therapy as an adjunct or alternative to standard medical therapy, the evidence includes an RCT and nonrandomized comparative studies. Relevant outcomes are overall

survival, disease-specific survival, quality of life, and treatment-related morbidity. The single RCT evaluating TTF therapy for recurrent GBM did not show superiority of TTF therapy for the primary outcome (overall survival) compared with physicians' choice chemotherapy. Because no serious adverse effects have been identified with TTF therapy, this raises the possibility that treatment with TTF might reduce the toxicity associated with treatment for recurrent GBM. A reduction in chemotherapy-associated toxicity without loss of efficacy would be considered a net health benefit. However, this RCT is not sufficient to permit conclusions on the efficacy of the device. Because the trial was not designed as a noninferiority trial, no inferences of noninferiority compared with chemotherapy can be made. Also, quality of life assessment was measured in an insufficient number of patients to reach firm conclusions on differences in quality of life between TTF therapy and medical treatment. The highest quality study of TTF combined with medical treatment for recurrent GBM is a post hoc analysis of the EF-14 trial. A high-quality, prospective RCT is needed. The evidence is insufficient to determine the effects of the technology on health outcomes.

## **Supplemental Information**

### **Clinical Input From Physician Specialty Societies and Academic Medical Centers**

While the various physician specialty societies and academic medical centers may collaborate with and make recommendations during this process, through the provision of appropriate reviewers, input received does not represent an endorsement or position statement by the physician specialty societies or academic medical centers, unless otherwise noted.

In response to requests, input was received from 3 physician specialty societies (one of which provided 6 responses and 2 of which provided 1 response each) and 1 academic medical center (total of 9 individual responses) while this policy was under review in 2016. There was majority support, but not consensus, for the use of tumor treatment fields therapy as an adjunct to maintenance treatment following initial therapy for glioblastoma multiforme. There was mixed support for the use of tumor treatment fields as an alternative to chemotherapy in advanced or recurrent glioblastoma multiforme.

### **Practice Guidelines and Position Statements**

National Comprehensive Cancer Network guidelines on central nervous system cancers (v.1.2018) include recommendations for the treatment of glioblastoma (see Table 11).<sup>3</sup> For the initial treatment of patients with glioblastoma with good performance status and either methylated or unmethylated or indeterminate O<sup>6</sup>-methylguanine-DNA methyltransferase promotor status, treatment with standard brain radiotherapy plus concurrent temozolomide and adjuvant temozolomide plus alternating electric field therapy is a category 1 recommendation. Alternating electric currents therapy is only an option for patients with supratentorial disease. Consideration of alternating electric field therapy for recurrent glioblastoma is a category 2B recommendation.

**Table 11. Guidelines for Adjuvant Treatment of Glioblastoma, by Age and Performance Status**

Age, y	KPS Score,%	Treatment Options	Category
≤70	≥60	<ul style="list-style-type: none"> <li>Standard RT plus concurrent and adjuvant temozolomide plus TTF</li> <li>Standard RT plus concurrent and adjuvant temozolomide</li> </ul>	1
≤70	<60	<ul style="list-style-type: none"> <li>Hypofractionated RT with/without concurrent or adjuvant temozolomide</li> <li>Temozolomide</li> <li>Palliative/best supportive care</li> </ul>	2A
>70	≥60	<ul style="list-style-type: none"> <li>Hypofractionated RT plus concurrent and adjuvant temozolomide</li> <li>Standard RT plus concurrent and adjuvant temozolomide plus TTF</li> <li>Temozolomide alone</li> <li>Hypofractionated brain RT alone</li> </ul>	1
>70	<60	<ul style="list-style-type: none"> <li>Hypofractionated brain RT alone</li> <li>Temozolomide alone</li> <li>Palliative/best supportive care</li> </ul>	2A

KPS: Karnofsky Performance Status; RT: radiotherapy; TTF: tumor treating fields.

### U.S. Preventive Services Task Force Recommendations

Not applicable.

### Medicare National Coverage

There is no national coverage determination. In the absence of a national coverage determination, coverage decisions are left to the discretion of local Medicare carriers.

### Ongoing and Unpublished Clinical Trials

Some currently unpublished trials that might influence this review are listed in Table 12. Of particular note are the phase 3 trials evaluating TTF therapy in non-small-cell lung cancer and pancreatic cancer. TTF therapy is an active area of research for mechanisms underlying its effects on cancer cells.

**Table 12. Summary of Key Trials**

NCT No.	Trial Name	Planned Enrollment	Completion Date
<b>Ongoing</b>			
<b>NCT01971281<sup>a</sup></b>	A Phase II Study of TTFields (150 kHz) Concomitant With Gemcitabine and TTFields Concomitant With Gemcitabine Plus Nab-paclitaxel for Front-line Therapy of Advanced Pancreatic Adenocarcinoma	40	Dec 2017 (ongoing)
<b>NCT01894061<sup>a</sup></b>	A Prospective Phase II Trial of NovoTTF-100A With Bevacizumab (Avastin) in Patients With Recurrent Glioblastoma	40	Dec 2018
<b>NCT02663271<sup>a</sup></b>	A Phase 2, Multi-center, Single Arm, Histologically Controlled Study Testing the Combination of TTFields and Pulsed Bevacizumab Treatment in Patients With Bevacizumab-refractory	18	Mar 2019

NCT No.	Trial Name	Planned Enrollment	Completion Date
<b>NCT02831959<sup>a</sup></b>	Recurrent Glioblastoma Pivotal, Open-label, Randomized Study of Radiosurgery With or Without Tumor Treating Fields (TTFields) (150kHz) for 1-10 Brain Metastases From Non-small Cell Lung Cancer (NSCLC) (METIS)	270	Jul 2019
<b>NCT02973789<sup>a</sup></b>	LUNAR: Pivotal, Randomized, Open-label Study of Tumor Treating Fields (TTFields) Concurrent With Standard of Care Therapies for Treatment of Stage 4 Non-small Cell Lung Cancer (NSCLC) Following Platinum Failure	534	Dec 2021
<b>NCT02743078<sup>a</sup></b>	Phase II Trial Of Optune® Plus Bevacizumab In Bevacizumab-Refractory Recurrent Glioblastoma	85	Aug 2022
<b>NCT03377491<sup>a</sup></b>	EF-27 Pivotal, Randomized, Open-label Study of Tumor Treating Fields (TTFields, 150kHz) Concomitant With Gemcitabine and Nab-paclitaxel for Front-line Treatment of Locally-advanced Pancreatic Adenocarcinoma (PANOVA-3)	556	Dec 2022

NCT: national clinical trial.

<sup>a</sup> Denotes industry-sponsored or cosponsored trial.

Medical technology is constantly changing, and we reserve the right to review and update our policies periodically.

## POLICY

The use of FDA approved devices to generate electric tumor treatment fields (TTF) to treat histologically confirmed supratentorial glioblastoma (known also as glioblastoma multiforme [GBM] or World Health Organization [WHO] grade IV astrocytoma) is considered **medically necessary** as adjunctive treatment when all of the following criteria below are met:

1. Initial treatment with de-bulking surgery or biopsy followed by chemoradiation with concomitant temozolomide and radiotherapy has been completed with no documented tumor progression (see Policy Guidelines); and
2. TTF is initiated within 7 weeks of chemoradiation; and
3. TTF is used in combination with temozolomide; and
4. Individual has Karnofsky Performance Status score of 60 or higher and
5. Individual or caregiver has been trained and is willing and able to apply and maintain the device at least 18 hours every day.

When the above criteria are met, treatment may be authorized for up to 6 months. For treatment to be considered **medically necessary** beyond that time, the following criteria must be met:

1. Documentation is provided of compliance with proper device use for at least 18 hours a day.
2. Disease progression is not occurring despite treatment with TTF (See Policy Guidelines).

The use of devices to generate electric tumor treatment fields (TTF) is considered **investigational** when the criteria above are not met and for all other indications.

## POLICY GUIDELINES

Coverage for TTF may be allowed for up to 6 months with a medical necessity determination, and if the patient is shown to be compliant with the regimen. Continued use after 6 months will require additional documentation to show no progression of the tumor outside the radiation treatment field, worsening of the member's condition (e.g., Karnofsky performance status of < 60), or new symptoms of progressive disease.

Tumor progression may be radiologically defined as tumor growth greater than 25% compared to the

smallest measured tumor area or the appearance of one or more new GBM lesions in the brain. It is noted that pseudo-progression can appear as tumor progression on imaging and may actually be treatment effect. If pseudo-progression is identified, it must be supported through documentation by a neuro-radiologist.

There are no specific codes for the initial application of this system and instruction on use. The patient reapplies the transducer arrays at home after the initial instruction.

Effective in 2014, there are HCPCS codes for the system and the transducer arrays:

E0766: Electrical stimulation device, used for cancer treatment, includes all accessories, any type

A4555: Electrode/transducer for use with electrical stimulation device, used for cancer treatment, replacement only

**Table 1. Karnofsky Performance Status Scale<sup>17</sup>**

Condition	Value (%)	Level of Functional Capacity
Able to carry on normal activity and to work; no special care needed	100%	No complaints; no evidence of disease
	90%	Able to carry on normal activity; minor signs or symptoms of disease
	80%	Normal activity with effort; some signs or symptoms of disease
Unable to work; able to live at home and care for most personal needs; varying amount of assistance needed	70%	Cares for self; unable to carry on normal activity or to do active work
	60%	Requires occasional assistance but is able to care for most personal needs
	50%	Requires considerable assistance and frequent medical care
Unable to care for self; requires equivalent of institutional or hospital care; diseases may be progressing rapidly	40%	Disabled; requires special care and assistance
	30%	Severely disabled; hospital admission indicated although death not imminent
	20%	Very sick; hospital admission necessary; active supportive treatment necessary
	10%	Moribund; fatal processes progressing rapidly
	0%	Dead

## BENEFIT APPLICATION

### BLUE CARD/NATIONAL ACCOUNT ISSUES

State or federal mandates (e.g., FEP) may dictate that all U.S. Food and Drug Administration-approved devices, drugs, or biologics may not be considered investigational, and thus these devices may be assessed only on the basis of their medical necessity.

**BACKGROUND****GLIOBLASTOMA MULTIFORME**

Glioblastomas, also known as glioblastoma multiforme (GBM), are the most common form of malignant primary brain tumor in adults.<sup>1</sup> GBMs are grade IV astrocytomas, a rapidly progressing and deadly type of glial cell tumor that is often resistant to standard medical therapy (eg, bevacizumab, chemotherapy). Together, anaplastic astrocytomas and glioblastomas comprise approximately 38% of all brain and central nervous system tumors.<sup>1</sup> The peak incidence for GBM occurs between the ages of 45 and 70 years, with a median age at diagnosis of 64 years. Glioblastomas have the lowest survival rate of any central nervous system tumor; in one report, about a third of patients survived to 1 year, and the 5-year survival rate was around 5%.<sup>2</sup>

**Clinical Context and Therapy Purpose**

The purpose of alternating electrical field therapy, more commonly known as tumor treating fields (TTF) therapy, is to provide a treatment option that is better than existing therapies for GBM. TTF has been investigated as an adjunct to temozolomide for the treatment of newly diagnosed GBM and as an alternative or adjunct to medical therapy for progressive or recurrent GBM

***Treatment of Newly Diagnosed GBM***

The primary treatment for patients newly diagnosed with GBM is to resect the tumor to confirm a diagnosis while debulking the tumor to relieve symptoms of increased intracranial pressure or compression. If total resection is not feasible, subtotal resection and open biopsy are options. During surgery, some patients may undergo implantation of the tumor cavity with a carmustine (bis-chloroethylnitrosourea) impregnated wafer. Due to the poor efficacy of local treatment, postsurgical treatment with adjuvant radiotherapy, chemotherapy (typically temozolomide), or a combination of these 2 therapies is recommended. After adjuvant therapy, patients may undergo maintenance therapy with temozolomide. Maintenance temozolomide is given for 5 days of every 28-day cycle for 6 cycles. Response and overall survival rates with temozolomide are higher in patients who have O6-methylguanine-DNA methyltransferase (MGMT) gene promoter methylation (see 2.04.113 on MGMT promoter methylation for malignant gliomas).

Prognostic factors for therapy success are age, histology, performance status or physical condition of the patient, and extent of resection. National Comprehensive Cancer Network recommendations include patient age and Karnofsky Performance Status score as important determinants of postsurgical treatment choice (see the Supplemental Information section).<sup>3</sup> For patients with good performance status, the most aggressive treatment (standard radiotherapy [RT] plus temozolomide) is recommended. For patients with poor performance status, only single treatment cycles or even palliative or supportive care are recommended. Hypofractionated RT is indicated for patients with poor performance status because it is better tolerated, and more patients are able to complete RT.

Treatment of GBM is rarely curative, and tumors will recur essentially all patients.

***Treatment of Recurrent GBM***

When disease recurs, additional debulking surgery may be used if the recurrence is localized. Due to radiation tolerances, re-radiation options for patients with recurrent GBM who have previously received initial external-beam radiotherapy are limited. There is no standard adjunctive treatment for recurrent GBM. Treatment options for recurrent disease include various forms of systemic medications such as the

antivascular endothelial growth factor drug bevacizumab, alkylating agents such as nitrosoureas (eg, lomustine, carmustine), or retreatment with temozolomide. Medical therapy is associated with side effects that include hematologic toxicity, headache, loss of appetite, nausea, vomiting, and fatigue. Response rates in recurrent disease are less than 10%, and the progression-free survival rate at 6 months is less than 20%.<sup>4</sup> There is a need for new treatments that can improve survival in patients with recurrent GBM or reduce the side effects of treatment while retaining survival benefits.

The questions addressed in this evidence review are:

- Does TTF, when used as an adjunct to maintenance medical therapy in patients with newly diagnosed GBM, improve the net health outcome?
- Does TTF, when used as an adjunct to medical therapy in patients with recurrent GBM, improve the net health outcome?
- Does TTF, when used as an alternative to medical therapy in patients with recurrent GBM, improve the net health outcome?

The following PICOTS were used to select literature to inform this review.

### ***Patients***

The relevant populations of interest are patients who have newly diagnosed GBM with good performance status or patients with recurrent GBM with good performance status. Newly diagnosed patients would have undergone initial treatment with surgery, RT, and chemotherapy and be receiving maintenance chemotherapy.

### ***Interventions***

TTF therapy is a noninvasive technology intended to treat GBM on an outpatient basis and at home using electrical fields.<sup>4-6</sup> TTF therapy exposes rapidly dividing cancer cells to electric fields of low intensity and intermediate frequency (200 kHz) that alternate in perpendicular orientation. TTF therapy is proposed to inhibit tumor growth by 2 mechanisms: the arrest of cell proliferation by causing microtubule misalignment in the mitotic spindle of rapidly dividing tumor cells and apoptosis due to movement of macromolecules and organelles during telophase.<sup>5,6</sup> Preclinical studies have indicated that the electric fields may also make the cells more susceptible to chemotherapy.

Optune (formerly NovoTTF-100A System) is the only legally marketed TTF delivery system available in the United States. The portable, battery-powered device is carried in a backpack or shoulder pack while carrying out activities of daily living. For the treatment of glioblastoma, 4 disposable transducer arrays with insulated electrodes are applied to the patient's shaved head. The transducer array layout is typically determined using specialized software. The patient's scalp is re-shaved and the transducer arrays replaced twice a week by the patient, caregiver, or device technician. The device is worn for up to 24 hours a day for the duration of treatment, except for brief periods for personal hygiene and 2 to 3 days at the end of each month. The minimum daily treatment is 18 hours. The minimum duration of treatment is 1 month, with the continuation of treatment available until recurrence.

### ***Comparators***

The following practice is currently being used to make decisions about newly diagnosed GBM: maintenance chemotherapy with temozolomide alone.

The following practices are currently being used to make decisions about recurrent GBM: medical therapy.

TTF therapy might also be compared with palliative or supportive care, where survival rarely exceeds 3 to 5 months.<sup>4</sup>

### **Outcomes**

The general outcomes of interest are whether TTF improves survival or quality of life during treatment and, because most GBMs recur, the time to tumor recurrence. Measures of cognitive status and quality of life measures are also of interest to determine whether TTF alters the decline in cognition and quality of life that occur with GBM. Also, adverse events of treatment such as side effects of chemotherapy and the possibility of seizures need to be assessed.

### **Timing**

Due to the rapid progression of GBM, the time of interest for both progression-free survival and overall survival is months.

### **Setting**

The setting is outpatient care by an oncologist or neuro-oncologist.

## **REGULATORY STATUS**

In April 2011, the NovoTTF-100A™ System (Novocure; assigned the generic name of TTF) was approved by the U.S. Food and Drug Administration (FDA) through the premarket approval process.<sup>7</sup> The FDA-approved label reads as follows: “The NovoTTF-100A System is intended as a treatment for adult patients (22 years of age or older) with confirmed GBM, following confirmed recurrence in an upper region of the brain (supratentorial) after receiving chemotherapy. The device is intended to be used as a stand-alone treatment and is intended as an alternative to standard medical therapy for recurrent GBM after surgical and radiation options have been exhausted.”

In September 2014, FDA approved Novocure’s request for a product name change from NovoTTF-110A System to Optune®.<sup>8</sup>

In October 2015, FDA expanded the indication for Optune® in combination with temozolomide to include newly diagnosed GBM.<sup>9</sup> The device was granted priority review status in May 2015 because there was no legally marketed alternative device available for the treatment of newly diagnosed GBM, a life-threatening condition. In July 2016, a smaller, lighter version of the Optune® device, called the Optune® System (NovoTTF-200A System), received FDA approval.

The FDA-approved label for newly diagnosed GBM reads as follows: “This device is indicated as treatment for adult patients (22 years of age or older) with histologically-confirmed glioblastoma multiforme (GBM). Optune™ with temozolomide is indicated for the treatment of adult patients with newly diagnosed, supratentorial glioblastoma following maximal debulking surgery and completion of radiation therapy together with concomitant standard of care chemotherapy.”

FDA product code: NZK.

## **RATIONALE**

This evidence review was created in August 2013 and has been updated regularly with searches of the MEDLINE database. The most recent literature update was performed through April 5, 2018.

Evidence reviews assess the clinical evidence to determine whether the use of a technology improves the net health outcome. Broadly defined, health outcomes are length of life, quality of life, and ability to function—including benefits and harms. Every clinical condition has specific outcomes that are

important to patients and to managing the course of that condition. Validated outcome measures are necessary to ascertain whether a condition improves or worsens; and whether the magnitude of that change is clinically significant. The net health outcome is a balance of benefits and harms.

To assess whether the evidence is sufficient to draw conclusions about the net health outcome of a technology, 2 domains are examined: the relevance and the quality and credibility. To be relevant, studies must represent one or more intended clinical use of the technology in the intended population and compare an effective and appropriate alternative at a comparable intensity. For some conditions, the alternative will be supportive care or surveillance. The quality and credibility of the evidence depend on study design and conduct, minimizing bias and confounding that can generate incorrect findings. The randomized controlled trial (RCT) is preferred to assess efficacy; however, in some circumstances, nonrandomized studies may be adequate. RCTs are rarely large enough or long enough to capture less common adverse events and long-term effects. Other types of studies can be used for these purposes and to assess generalizability to broader clinical populations and settings of clinical practice.

For this review, 3 indications are evaluated: (1) tumor treating fields (TTF) as an adjunct to maintenance chemotherapy in newly diagnosed patients following initial treatment with surgery, radiotherapy and chemotherapy and (2) TTF as an adjunct or (3) alternative to medical therapy (eg, bevacizumab, chemotherapy) in progressive or recurrent glioblastoma multiforme (GBM).

### ***Study Selection***

The PICOTS was used to select relevant studies.

- To assess efficacy outcomes, comparative controlled prospective trials were sought, with a preference for RCTs.
- To assess longer term outcomes and adverse events, single-arm studies that capture longer periods of follow-up and/or larger populations were sought.
- Within each category of study design, studies with larger sample size studies and longer duration were sought.

## **TTF THERAPY AS AN ADJUNCT TO STANDARD MAINTENANCE CARE FOR NEWLY DIAGNOSED GBM**

### **Randomized Controlled Trials**

Stupp et al (2017) published results of the EF-14 multicenter, open-label phase 3 RCT that evaluated maintenance therapy with TTF for newly diagnosed GBM.<sup>10</sup> The trial included 695 patients from 83 sites who had supratentorial GBM and had completed standard treatment consisting of biopsy or surgical resection followed by radiotherapy and chemotherapy (see Table 1). A Karnofsky Performance Status (KPS) score of 70 or higher was an additional inclusion criterion to ensure independence in activities of daily living, and patients with rapidly progressing GBM following radiochemotherapy were excluded from the trial. Patients were randomized in a 2:1 fashion to TTF plus maintenance temozolomide or maintenance temozolomide alone.

All patients were seen monthly for follow-up. Quality of life (QOL) was assessed every 3 months, and magnetic resonance imaging (MRI) was performed every 2 months until tumor progression. Tumor progression on MRI was adjudicated by a central review committee blinded to treatment group. The primary outcome was progression-free survival (PFS), and the secondary outcome was overall survival (OS). The analysis was by intention-to-treat, including 26 patients from the control arm who crossed over to TTF following the planned interim analysis.

In 2014, an independent data and safety monitoring board concluded from the planned interim analysis that the trial met its predefined boundaries for success (improvement in PFS and OS) and recommended

trial termination. The Food and Drug Administration approved the trial termination, and the trial was closed to recruitment with 695 of the planned 700 participants randomized. Control arm participants were allowed to cross over to the experimental treatment at this time. The interim analysis, which the Food and Drug Administration considered for the 2015 expanded approval of Optune, was published by Stupp et al (2015).<sup>11</sup> At the time of the interim analysis, data were available for 210 patients randomized to TTF plus temozolomide and 105 patients to temozolomide alone. Follow-up of the remainder of the 695 enrolled patients continued after enrollment was closed.

Stupp et al (2017) <sup>10</sup> ; EF-14	U.S., E.U., South Korea, Israel	83	2009-2016	<ul style="list-style-type: none"> <li>695 newly diagnosed with GBM and treated by radiochemotherapy</li> <li>KPS score <math>\geq 70</math></li> </ul>	TTF >18 h/d plus maintenance temozolomide (n=466)	Maintenance temozolomide alone (5 d every 28 d for 6 cycles) (n=229)

GBM: glioblastoma multiforme; h/d; hours per day; KPS: Karnofsky Performance Status; TTF: tumor treatment fields.

Results of the final analysis of the EF-14 trial were similar to the interim analysis and are shown in Table 2. Both PFS and OS improved with the addition of TTF therapy to standard maintenance chemotherapy (ie, temozolomide). PFS increased by 2.7 mo ( $p < 0.001$ ) and OS increased by 4.9 mo ( $p < 0.001$ ) in the TTF group. The time to a decrease in mental function was 2.5 months longer with TTF therapy ( $p < 0.01$ ).

There was a similar percentage of dropouts at the final analysis—with 49 (11%) patients in the TTF group and 27 (12%) patients in the temozolomide alone group. More treatment cycles with temozolomide were administered in the TTF group (median, 6 for TTF group vs 5 for controls), a finding that is consistent with the longer PFS. Rates of adverse events were similar between the groups, including rates of seizures. In secondary analysis of patients who had not progressed, there was no reduction in health-related quality of life with TTF compared with temozolomide alone aside from “itchy skin”.<sup>12</sup> Interpretation of this result is limited by the low percentage of patients who completed the health-related quality of life assessments at follow-up (65.8% of the 655 patients alive at 3 months and 41.7% of the 473 patients alive at 12 months). A mixed-model analysis, which accounts for missing data, confirmed the results of the mean change from baseline analysis.

**Table 2. Key Randomized Controlled Trial Results for Newly Diagnosed Glioblastoma**

CI: confidence interval; HR: hazard ratio; MMSE: Mini-Mental State Examination; OS: overall survival; PFS: progression-free survival; TTF: tumor treatment fields.

Tables 3 and 4 display notable gaps identified in this trial, the major limitation is the lack of patient blinding to treatment assignment. However, PFS was assessed by investigators who were blinded to treatment and placebo effects on OS were expected to be minimal. Investigators considered it practically unfeasible (due to the heat and current of the TTF therapy) and ethically unacceptable to submit the control patients to repeated shaving of the head and continuous wear of a sham device over many months.

### Section Summary: TTF Therapy as an Adjunct to Standard Maintenance Care for Newly Diagnosed GBM

The final analysis of the EF-14 trial, which included 695 patients from 83 sites, found a statistically and clinically significant increase of 2.7 months in PFS and an increase of 4.9 months in OS with the addition of TTF therapy to standard maintenance therapy (ie, temozolomide) in patients with newly diagnosed GBM. There was no sham control, and patients were not blinded to treatment assignment, but PFS was assessed by blinded evaluators, and placebo effects on the objective measure of OS were likely to be minimal. There was no evidence of a negative impact of TTF therapy on health-related quality of life, except for itchy skin from the transducers.

### TTF THERAPY AS AN ADJUNCT OR ALTERNATIVE TO MEDICAL THERAPY FOR PROGRESSIVE OR RECURRENT GBM

#### Randomized Controlled Trials

The 2011 Food and Drug Administration approval of the NovoTTF-100A System (now called Optune) was based on a phase 3 multinational RCT (EF-11), results of which were published by Stupp et al (2012).<sup>4</sup> This trial compared TTF therapy alone with physician's choice medical therapy in 237 adults who had relapsed or progressive glioblastoma (see Table 5). Patients had failed conventional treatment with radiotherapy, chemotherapy, and/or surgery, and more than 80% of participants had failed 2 or more prior chemotherapy regimens. In this trial, the term chemotherapy also applied to targeted agents such as bevacizumab. Patient characteristics and performance of additional post-recurrence debulking surgery were similar in the 2 groups.

**Table 5. Summary of Key Randomized Controlled Trial Characteristics for Progressive or Recurrent Glioblastoma**

Study; Trial	Countries	Sites	Dates	Participants	Interventions	
					Active	Comparator
Stupp et al (2012) <sup>4</sup> ; EF-11	U.S., E.U., Israel	28	1987-2013	• 237 adults with relapsed or progressive supratentorial glioblastoma	120 patients treated with TTF alone, 93 (78%) completed 1	117 patients treated with physician's choice of medical therapy <sup>a</sup>

• KPS score  $\geq 70\%$  cycle

EU: European Union; KPS: Karnofsky Performance Status; TTF: tumor treating fields.

<sup>a</sup> Medical therapy included bevacizumab, irinotecan, nitrosoureas, platinum-based chemotherapy (ie, carboplatin); temozolomide; or a combination of procarbazine, chloroethyl ether, and vincristine.

Participants were followed monthly, including laboratory tests. MRI images were evaluated at 2, 4, and 6 months from initiation of treatment, with subsequent MRIs performed according to local practice until disease progression. QOL questionnaires were completed every 3 months. Medical follow-up continued for 2 months after disease progression. Monthly telephone interviews with participants' caregivers were used to assess mortality rates. The primary end point was OS. Secondary end points included PFS, the percentage of patients with PFS at 6 months, time to progression, 1-year survival rate, QOL, and radiologic response. All end points were evaluated using intention-to-treat analysis.

The trial did not reach its primary end point of improved survival compared with active medical therapy (see Table 6). With a median follow-up of 39 months, 93% of patients had died. There was not a statistically significant difference in survival rates at 1, 2, and 3 years between groups. Patients in the TTF group did not, however, suffer the typical systemic side effects of chemotherapy. The most common adverse event in the TTF group was grade 1 and 2 contact dermatitis on the scalp, which resolved with topical corticosteroids and did not require treatment breaks. Control participants experienced grade 2, 3, or 4 events by organ system related to the pharmacologic activity of chemotherapy agents used. Hematologic events of grade 2 or greater were observed in 17% of chemotherapy patients compared with 3% of TTF patients. Gastrointestinal disorders of grade 2 or greater were identified in 17% of chemotherapy patients compared with 4% of TTF patients. Severe (grades 3-4) hematologic and gastrointestinal toxicity was observed in 7% of chemotherapy controls compared with 1% of the TTF group.

Longitudinal QOL data, available in 63 (27%) participants, showed no meaningful differences between groups for the domains of global health and social functioning. However, cognitive and emotional functioning domains favored TTF therapy. Symptom scale analysis was by treatment-associated toxicity; appetite loss, diarrhea, constipation, nausea, and vomiting were directly related to the chemotherapy administration.

The trial had a number of limitations (see Tables 7 and 8), that included lack of blinding and high loss to follow-up. Discontinuation of TTF therapy occurred in 22% of patients due to noncompliance or inability to handle the device, usually within the first few days. In the control group, 21 (18%) patients did not return to the treatment site, and details on disease progression and toxicity were not available. Longitudinal QOL could be analyzed only for 27% of patients who remained on study therapy for 3 months. The trial was designed as a superiority trial and did not provide adequate evidence of noninferiority.

### Nonrandomized Comparative Studies

Kesari et al (2017) conducted a post hoc analysis of the EF-14 trial (see Stupp et al [2017] above) to evaluate the efficacy of TTF in patients who had the first recurrence.<sup>13</sup> Some patients in the temozolomide alone group crossed over to receive TTF plus chemotherapy after the first recurrence, resulting in 144 patients who received TTF fields plus chemotherapy and 60 patients who received chemotherapy alone for recurrent GBM (see Table 9). Patient characteristics and second-line treatments were well-balanced between the groups, with bevacizumab the most common second-line therapy. The median OS in patients treated with systemic therapy alone was 9.2 months (see Table 10). In comparison, the group of patients who received TTF therapy in addition to systemic therapy had a median OS of 11.8 months (p=0.043).

A registry study published Mrugala et al (2014) assessed OS data from patients who received NovoTTF therapy in a real-world, clinical practice setting (see Table 9).<sup>14</sup> Concurrent treatment was not captured in the registry, and it is possible that some patients received combination therapy. Median OS in the PRiDe clinical practice dataset (9.6 mo) was reported as superior to that attained in the EF-11 pivotal trial (6.6 mo, p<0.001) (see Table 10). More patients in the PRiDe registry were treated for first recurrence (33% vs 9%), and more had received bevacizumab as prior therapy (55% vs 19%). The PRiDe investigators reported no novel or unexpected treatment-related adverse events compared with the EF-11 trial.

P value	<0.001		

CI: confidence interval; OS: overall survival, TTF: tumor treating fields.

Post hoc analyses of the EF-11 pivotal trial have been reported. Wong et al (2014) published a subgroup analysis to determine characteristics of responders and nonresponders in the active treatment and active treatment control.<sup>15</sup> They found that responders had a lower grade of histology and lower daily dexamethasone use than nonresponders. A second post hoc analysis by Kanner et al (2014) of the EF-11 pivotal trial data was performed to evaluate OS among patients who finished at least 1 complete course of TTF or chemotherapy.<sup>16</sup> The investigators reported that median OS was 7.7 months in the TTF group compared with 5.9 months in the chemotherapy group (p=0.009). These post hoc analyses are considered to be hypothesis-generating.

#### Section Summary: TTF Therapy as an Adjunct or Alternative to Chemotherapy for Progressive or Recurrent GBM

The single RCT for TTF as an alternative to chemotherapy reported that outcomes following TTF therapy were similar to outcomes following standard chemotherapy. However, this RCT is not sufficient to permit conclusions on the efficacy of the device. The noninferiority of TTF compared with chemotherapy might be considered a sufficient health benefit, if TTF reduced treatment toxicity. However, because the trial was not designed as a noninferiority trial no inferences of noninferiority compared with chemotherapy can be made. Physician's choice therapy during the trial was heterogeneous, although analysis indicated that survival was not affected by choice of chemotherapy. More patients in the TTF group than in the control group did not complete the treatment course. The number of patients who contributed QOL data was approximately one-quarter of total enrollment, and the self-reported QOL indicators might have been subject to bias due to the lack of blinding.

A nonrandomized post hoc evaluation of the EF-14 trial suggests that TTF may improve survival when combined with chemotherapy for recurrent GBM. This analysis should be considered hypothesis-generating, and further study in high-quality RCTs is needed.

#### SUMMARY OF EVIDENCE

For individuals who have newly diagnosed GBM on maintenance therapy after initial treatment who receive TTF therapy as an adjunct to standard maintenance therapy, the evidence includes an RCT. Relevant outcomes include overall survival, disease-specific survival, symptoms, functional outcomes, quality of life, and treatment-related morbidity. The EF-14 trial found a significant increase of 2.7 months in progression-free survival and an increase of 4.9 months in overall survival with the addition of TTF therapy to standard maintenance therapy (ie, temozolomide) in patients with newly diagnosed GBM. Although patients were not blinded to treatment assignment, progression-free survival was

assessed by blinded evaluators, and the placebo effects on the objective measure of overall survival are expected to be minimal. This technology represents a clinically significant option in the treatment of patients with GBM, for whom options are limited. The evidence is sufficient to determine that the technology results in a meaningful improvement in the net health outcome.

For individuals who have progressive or recurrent GBM who receive TTF therapy as an adjunct or alternative to standard medical therapy, the evidence includes an RCT and nonrandomized comparative studies. Relevant outcomes are overall survival, disease-specific survival, quality of life, and treatment-related morbidity. The single RCT evaluating TTF therapy for recurrent GBM did not show superiority of TTF therapy for the primary outcome (overall survival) compared with physicians' choice chemotherapy. Because no serious adverse effects have been identified with TTF therapy, this raises the possibility that treatment with TTF might reduce the toxicity associated with treatment for recurrent GBM. A reduction in chemotherapy-associated toxicity without loss of efficacy would be considered a net health benefit. However, this RCT is not sufficient to permit conclusions on the efficacy of the device. Because the trial was not designed as a noninferiority trial, no inferences of noninferiority compared with chemotherapy can be made. Also, quality of life assessment was measured in an insufficient number of patients to reach firm conclusions on differences in quality of life between TTF therapy and medical treatment. The highest quality study of TTF combined with medical treatment for recurrent GBM is a post hoc analysis of the EF-14 trial. A high-quality, prospective RCT is needed. The evidence is insufficient to determine the effects of the technology on health outcomes.

#### SUPPLEMENTAL INFORMATION

##### CLINICAL INPUT FROM PHYSICIAN SPECIALTY SOCIETIES AND ACADEMIC MEDICAL CENTERS

While the various physician specialty societies and academic medical centers may collaborate with and make recommendations during this process, through the provision of appropriate reviewers, input received does not represent an endorsement or position statement by the physician specialty societies or academic medical centers, unless otherwise noted.

In response to requests, input was received from 3 physician specialty societies (one of which provided 6 responses and 2 of which provided 1 response each) and 1 academic medical center (total of 9 individual responses) while this policy was under review in 2016. There was majority support, but not consensus, for use of tumor treatment field's therapy as an adjunct to maintenance treatment following initial therapy for glioblastoma multiforme. There was mixed support for use of tumor treatment fields as an alternative to chemotherapy in advanced or recurrent glioblastoma multiforme.

**PRACTICE GUIDELINES AND POSITION STATEMENTS** National Comprehensive Cancer Network guidelines on central nervous system cancers (v.1.2018) include recommendations for the treatment of glioblastoma (see Table 11).<sup>3</sup> For the initial treatment of patients with glioblastoma with good performance status and either methylated or unmethylated or indeterminate O<sup>6</sup>-methylguanine-DNA methyltransferase promotor status, treatment with standard brain radiotherapy plus concurrent temozolomide and adjuvant temozolomide plus alternating electric field therapy is a category 1 recommendation. Alternating electric currents therapy is only an option for patients with supratentorial disease. Consideration of alternating electric field therapy for recurrent glioblastoma is a category 2B recommendation.

**Table 11. Guidelines for Adjuvant Treatment of Glioblastoma, by Age and Performance Status**

KPS: Karnofsky Performance Status; RT: radiotherapy; TTF: tumor treating fields.

#### U.S. PREVENTIVE SERVICES TASK FORCE RECOMMENDATIONS

Not applicable.

#### MEDICARE NATIONAL COVERAGE

There is no national coverage determination. In the absence of a national coverage determination, coverage decisions are left to the discretion of local Medicare carriers.

#### ONGOING AND UNPUBLISHED CLINICAL TRIALS

Some currently unpublished trials that might influence this review are listed in Table 12. Of particular note are the phase 3 trials evaluating TTF therapy in non-small-cell lung cancer and pancreatic cancer. TTF therapy is an active area of research for mechanisms underlying its effects on cancer cells.

#### CODES

Codes	Number	Description
CPT Codes		No specific CPT code- See Policy Guidelines
	191.0-191.9	Malignant neoplasm of brain code range
HCPCS Codes	A4555	Electrode/transducer for use with electrical stimulation device, used for cancer treatment, replacement only
	E0766	Electrical stimulation device, used for cancer treatment, includes all accessories, any type
ICD-10-CM		Investigational for all relevant diagnoses
	C71.0-C71.9	Malignant neoplasm of brain code range
ICD-10-PCS		Not applicable. Policy is only for outpatient services. ICD-10-PCS codes are only used for inpatient services.
Type of Service		
Place of Service		

#### POLICY HISTORY

Date	Action	Description
08/14/14	Replace policy	Policy updated with literature review through June 26, 2014.

		References 8 and 16-17 added. Editorial revisions made to rationale section. Policy statement unchanged.
08/13/15	Replace policy	Policy updated with literature review through July 8, 2015; references 10-11 removed and 10-12 added. Policy statement unchanged.
08/11/16	Replace policy	Policy updated with literature review through July 18, 2016, and results of clinical vetting; reference 13 added. Policy statements rewritten for clarity but tumor treating fields remains investigational for all indications.
12/23/2016	Replace policy	Blue Cross of Idaho adopted new policy statement and policy guidelines to reflect NCCN 2A recommendations. Medically necessary indication with specific criteria.
07/25/17	Replace policy	Blue Cross of Idaho adopted changes as noted, with no change to policy statements. Policy updated with literature review through June 5, 2017; no references added. No change to policy statements or policy guidelines.
03/29/18	Update only	Medical policy renumbered from 1.01.29 to 1.01.529.
06/27/18	Replace policy	Policy updated with literature review through April 5, 2018; references 10, and 12-13, and 17 added. No change to policy statements or policy guidelines.

# Protocol

## Tumor Treating Fields Therapy

(10129)

(Formerly Tumor Treatment Fields Therapy for Glioblastoma)

Medical Benefit		Effective Date: 10/01/18	Next Review Date: 07/19
Preauthorization	Yes	Review Dates: 09/15, 05/16, 09/16, 09/17, 07/18	

### Preauthorization is required.

The following protocol contains medical necessity criteria that apply for this service. The criteria are also applicable to services provided in the local Medicare Advantage operating area for those members, unless separate Medicare Advantage criteria are indicated. If the criteria are not met, reimbursement will be denied and the patient cannot be billed. Please note that payment for covered services is subject to eligibility and the limitations noted in the patient's contract at the time the services are rendered.

### DESCRIPTION

Glioblastoma multiforme (GBM) is the most common and deadly malignant brain tumor. It has a very poor prognosis and is associated with low quality of life during of treatment. Tumor treatment fields (TTF) therapy is a new, noninvasive technology intended to treat glioblastoma using alternating electric fields.

### SUMMARY OF EVIDENCE

For individuals who have newly diagnosed GBM on maintenance therapy after initial treatment who receive TTF therapy as an adjunct to standard maintenance therapy, the evidence includes a randomized controlled trial (RCT). Relevant outcomes include overall survival, disease-specific survival, symptoms, functional outcomes, quality of life, and treatment-related morbidity. The EF-14 trial found a significant increase of 2.7 months in progression-free survival and an increase of 4.9 months in overall survival with the addition of TTF therapy to standard maintenance therapy (i.e., temozolomide) in patients with newly diagnosed GBM. Although patients were not blinded to treatment assignment, progression-free survival was assessed by blinded evaluators, and the placebo effects on the objective measure of overall survival are expected to be minimal. This technology represents a clinically significant option in the treatment of patients with GBM, for whom options are limited.

The evidence is sufficient to determine that the technology results in a meaningful improvement in the net health outcome.

For individuals who have progressive or recurrent GBM who receive TTF therapy as an adjunct or alternative to standard medical therapy, the evidence includes an RCT and nonrandomized comparative studies. Relevant outcomes are overall survival, disease-specific survival, quality of life, and treatment-related morbidity. The single RCT evaluating TTF therapy for recurrent GBM did not show superiority of TTF therapy for the primary outcome (overall survival) compared with physicians' choice chemotherapy. Because no serious adverse effects have been identified with TTF therapy, this raises the possibility that treatment with TTF might reduce the toxicity associated with treatment for recurrent GBM. A reduction in chemotherapy-associated toxicity without loss of efficacy would be considered a net health benefit. However, this RCT is not sufficient to permit conclusions on the efficacy of the device. Because the trial was not designed as a noninferiority trial, no inferences of noninferiority compared with chemotherapy can be made. Also, quality of life assessment was measured in an insufficient number of patients to reach firm conclusions on differences in quality of life between TTF therapy and medical treatment. The highest quality study of TTF combined with medical treatment for recurrent GBM is a post hoc analysis of the EF-14 trial. A high-quality, prospective RCT is needed. The evidence is insufficient to determine the effects of the technology on health outcomes.

## POLICY

Tumor treating fields therapy to treat glioblastoma multiforme is considered **medically necessary** as an adjunct to standard maintenance therapy with temozolomide in patients with newly diagnosed glioblastoma multiforme following initial treatment with surgery, radiotherapy, and/or chemotherapy under the following conditions:

- Adult patients  $\geq 22$  years of age
- Supratentorial tumor
- Karnofsky Performance Status score  $\geq 70\%$
- Patient understands device use, including the requirement for a shaved head, and is willing to comply with use criteria according to the Food and Drug Administration label (see Policy Guidelines).

Tumor treating fields therapy is considered **investigational** in all other conditions, including but not limited to the following situations:

- As an adjunct to standard medical therapy (e.g., bevacizumab, chemotherapy) for patients with progressive or recurrent glioblastoma multiforme
- As an alternative to standard medical therapy for patients with progressive or recurrent glioblastoma multiforme
- For brain metastases
- For cancer in areas other than the brain.

## POLICY GUIDELINES

Progression was defined in the EF-14 trial (Stupp et al [2015, 2017]) according to the MacDonald criteria (tumor growth  $> 25\%$  compared with the smallest tumor area measured in the patient during the trial or appearance of one or more new tumors in the brain that are diagnosed radiologically as glioblastoma multiforme).

The Food and Drug Administration label includes the following notices:

- Patients should use Optune for at least 18 hours a day to get the best response to treatment
- Patients should finish at least four full weeks of therapy to get the best response to treatment. Stopping treatment before four weeks lowers the chances of a response to treatment.

## MEDICARE ADVANTAGE

For Medicare Advantage tumor-treatment fields therapy is considered **not medically necessary**.

## BACKGROUND

### GLIOBLASTOMA MULTIFORME

Glioblastomas, also known as glioblastoma multiforme (GBM), are the most common form of malignant primary brain tumor in adults.<sup>1</sup> GBMs are grade IV astrocytomas, a rapidly progressing and deadly type of glial cell tumor that is often resistant to standard medical therapy (e.g., bevacizumab, chemotherapy). Together, anaplastic astrocytomas and glioblastomas comprise approximately 38% of all brain and central nervous system tumors.<sup>1</sup> The peak incidence for GBM occurs between the ages of 45 and 70 years, with a median age at diagnosis of 64 years. Glioblastomas have the lowest survival rate of any central nervous system tumor; in one report, about a third of patients survived to one year, and the five-year survival rate was around 5%.<sup>2</sup>

### Clinical Context and Therapy Purpose

The purpose of alternating electrical field therapy, more commonly known as TTF therapy, is to provide a treatment option that is better than existing therapies for GBM. TTF has been investigated as an adjunct to temozolomide for the treatment of newly diagnosed GBM and as an alternative or adjunct to medical therapy for progressive or recurrent GBM.

### Treatment of Newly Diagnosed GBM

The primary treatment for patients newly diagnosed with GBM is to resect the tumor to confirm a diagnosis while debulking the tumor to relieve symptoms of increased intracranial pressure or compression. If total resection is not feasible, subtotal resection and open biopsy are options. During surgery, some patients may undergo implantation of the tumor cavity with a carmustine (bis-chloroethylnitrosourea) impregnated wafer. Due to the poor efficacy of local treatment, postsurgical treatment with adjuvant radiotherapy, chemotherapy (typically temozolomide), or a combination of these two therapies is recommended. After adjuvant therapy, patients may undergo maintenance therapy with temozolomide. Maintenance temozolomide is given for five days of every 28-day cycle for six cycles. Response and overall survival rates with temozolomide are higher in patients who have O6-methylguanine-DNA methyltransferase (MGMT) gene promoter methylation.

Prognostic factors for therapy success are age, histology, performance status or physical condition of the patient, and extent of resection. National Comprehensive Cancer Network recommendations include patient age and Karnofsky Performance Status score as important determinants of postsurgical treatment choice.<sup>3</sup> For patients with good performance status, the most aggressive treatment (standard radiotherapy [RT] plus temozolomide) is recommended. For patients with poor performance status, only single treatment cycles or even palliative or supportive care are recommended. Hypofractionated RT is indicated for patients with poor performance status because it is better tolerated, and more patients are able to complete RT.

Treatment of GBM is rarely curative, and tumors will recur essentially all patients.

## Treatment of Recurrent GBM

When disease recurs, additional debulking surgery may be used if the recurrence is localized. Due to radiation tolerances, re-radiation options for patients with recurrent GBM who have previously received initial external-beam radiotherapy are limited. There is no standard adjunctive treatment for recurrent GBM. Treatment options for recurrent disease include various forms of systemic medications such as the antivascular endothelial growth factor drug bevacizumab, alkylating agents such as nitrosoureas (e.g., lomustine, carmustine), or retreatment with temozolomide. Medical therapy is associated with side effects that include hematologic toxicity, headache, loss of appetite, nausea, vomiting, and fatigue. Response rates in recurrent disease are less than 10%, and the progression-free survival rate at six months is less than 20%.<sup>4</sup> There is a need for new treatments that can improve survival in patients with recurrent GBM or reduce the side effects of treatment while retaining survival benefits.

The questions addressed in this protocol are:

- Does TTF, when used as an adjunct to maintenance medical therapy in patients with newly diagnosed GBM, improve the net health outcome?
- Does TTF, when used as an adjunct to medical therapy in patients with recurrent GBM, improve the net health outcome?
- Does TTF, when used as an alternative to medical therapy in patients with recurrent GBM, improve the net health outcome?

The following PICOTS were used to select literature to inform this review.

### Patients

The relevant populations of interest are patients who have newly diagnosed GBM with good performance status or patients with recurrent GBM with good performance status. Newly diagnosed patients would have undergone initial treatment with surgery, RT, and chemotherapy and be receiving maintenance chemotherapy.

### Interventions

TTF therapy is a noninvasive technology intended to treat GBM on an outpatient basis and at home using electrical fields.<sup>4-6</sup> TTF therapy exposes rapidly dividing cancer cells to electric fields of low intensity and intermediate frequency (200 kHz) that alternate in perpendicular orientation. TTF therapy is proposed to inhibit tumor growth by two mechanisms: the arrest of cell proliferation by causing microtubule misalignment in the mitotic spindle of rapidly dividing tumor cells and apoptosis due to movement of macromolecules and organelles during telophase.<sup>5,6</sup> Preclinical studies have indicated that the electric fields may also make the cells more susceptible to chemotherapy.

Optune (formerly NovoTTF-100A System) is the only legally marketed TTF delivery system available in the United States. The portable, battery-powered device is carried in a backpack or shoulder pack while carrying out activities of daily living. For the treatment of glioblastoma,<sup>4</sup> disposable transducer arrays with insulated electrodes are applied to the patient's shaved head. The transducer array layout is typically determined using specialized software. The patient's scalp is re-shaved and the transducer arrays replaced twice a week by the patient, caregiver, or device technician. The device is worn for up to 24 hours a day for the duration of treatment, except for brief periods for personal hygiene and two to three days at the end of each month. The minimum daily treatment is 18 hours. The minimum duration of treatment is one month, with the continuation of treatment available until recurrence.

### Comparators

The following practice is currently being used to make decisions about newly diagnosed GBM: maintenance chemotherapy with temozolomide alone.

The following practices are currently being used to make decisions about recurrent GBM: medical therapy.

TTF therapy might also be compared with palliative or supportive care, where survival rarely exceeds three to five months.<sup>4</sup>

#### Outcomes

The general outcomes of interest are whether TTF improves survival or quality of life during treatment and, because most GBMs recur, the time to tumor recurrence. Measures of cognitive status and quality of life measures are also of interest to determine whether TTF alters the decline in cognition and quality of life that occur with GBM. Also, adverse events of treatment such as side effects of chemotherapy and the possibility of seizures need to be assessed.

#### Timing

Due to the rapid progression of GBM, the time of interest for both progression-free survival and overall survival is months.

#### Setting

The setting is outpatient care by an oncologist or neuro-oncologist.

### REGULATORY STATUS

In April 2011, the NovoTTF-100A™ System (Novocure; assigned the generic name of TTF) was approved by the U.S. Food and Drug Administration (FDA) through the premarket approval process.<sup>7</sup> The FDA-approved label reads as follows: “The NovoTTF-100A System is intended as a treatment for adult patients (22 years of age or older) with confirmed GBM, following confirmed recurrence in an upper region of the brain (supratentorial) after receiving chemotherapy. The device is intended to be used as a stand-alone treatment and is intended as an alternative to standard medical therapy for recurrent GBM after surgical and radiation options have been exhausted.”

In September 2014, the FDA approved Novocure’s request for a product name change from NovoTTF-110A System to Optune®.<sup>8</sup>

In October 2015, the FDA expanded the indication for Optune® in combination with temozolomide to include newly diagnosed GBM.<sup>9</sup> The device was granted priority review status in May 2015 because there was no legally marketed alternative device available for the treatment of newly diagnosed GBM, a life-threatening condition. In July 2016, a smaller, lighter version of the Optune® device, called the Optune® System (NovoTTF-200A System), received FDA approval.

The FDA-approved label for newly diagnosed GBM reads as follows: “This device is indicated as treatment for adult patients (22 years of age or older) with histologically-confirmed glioblastoma multiforme (GBM). Optune™ with temozolomide is indicated for the treatment of adult patients with newly diagnosed, supratentorial glioblastoma following maximal debulking surgery and completion of radiation therapy together with concomitant standard of care chemotherapy.”

FDA product code: NZK.

### Policy Statement

Tumor treating fields therapy to treat glioblastoma multiforme may be considered **medically necessary** as an adjunct to standard maintenance therapy with temozolomide in patients with **newly diagnosed** glioblastoma multiforme following initial treatment with surgery, radiotherapy, and/or chemotherapy under the following conditions:

- Adult patients 18 years old or older
- Supratentorial tumor
- Karnofsky Performance Status score greater than or equal to 60%
- Documentation the patient understands device use, including the requirement for a shaved head, use for at least 18 hours a day for a minimum of 4 weeks, and is willing to comply with use criteria according to the Food and Drug Administration label (see Policy Guidelines section)

Tumor treating fields therapy is considered **investigational** in all other conditions, including but not limited to the following situations:

- As an adjunct or alternative to standard medical therapy for progressive or recurrent tumors (e.g., bevacizumab, chemotherapy) for patients with **progressive or recurrent** glioblastoma multiforme\* (see Policy Guidelines section)
- For brain metastases
- For cancer in areas other than the brain

### Policy Guidelines

\*Use for progressive or recurrent disease is a level 2B recommendation in NCCN guidelines (as compared to level 1 for newly diagnosed). Typically, a category 1 or 2A recommendation is followed, but not 2B. Progression was defined in the EF-14 trial (Stupp et al [2015, 2017]) according to the MacDonald criteria (tumor growth greater than 25% compared with the smallest tumor area measured in the patient during the trial or appearance of 1 or more new tumors in the brain that are diagnosed radiologically as glioblastoma multiforme).

The Food and Drug Administration label includes the following notices:

- Patients should use Optune for at least 18 hours a day to get the best response to treatment
- Patients should finish at least 4 full weeks of therapy to get the best response to treatment. Stopping treatment before 4 weeks lowers the chances of a response to treatment

### Coding

There are no specific codes for the initial application of this system or instruction on use. The patient reapplies the transducer arrays at home after the initial instruction.

There are HCPCS codes for the system and the transducer arrays:

- **A4555:** Electrode/transducer for use with electrical stimulation device used for cancer treatment, replacement only
- **E0766:** Electrical stimulation device used for cancer treatment, includes all accessories, any type

## Description

Glioblastoma multiforme (GBM) is the most common and deadly malignant brain tumor. It has a very poor prognosis and is associated with low quality of life during of treatment. Tumor treatment fields (TTF) therapy is a new, noninvasive technology intended to treat glioblastoma using alternating electric fields.

- Intraoperative Radiotherapy
- Stereotactic Radiosurgery and Stereotactic Body Radiotherapy

## Benefit Application

Benefit determinations should be based in all cases on the applicable contract language. To the extent there are any conflicts between these guidelines and the contract language, the contract language will control. Please refer to the member's contract benefits in effect at the time of service to determine coverage or non-coverage of these services as it applies to an individual member.

Some state or federal mandates (e.g., Federal Employee Program [FEP]) prohibits plans from denying Food and Drug Administration (FDA)-approved technologies as investigational. In these instances, plans may have to consider the coverage eligibility of FDA-approved technologies on the basis of medical necessity alone.

## Regulatory Status

In April 2011, the NovoTTF-100A™ System (Novocure; assigned the generic name of TTF) was approved by the U.S. Food and Drug Administration (FDA) through the premarket approval process.<sup>7</sup> The FDA-approved label reads as follows: "The NovoTTF-100A System is intended as a treatment for adult patients (22 years of age or older) with confirmed GBM, following confirmed recurrence in an upper region of the brain (supratentorial) after receiving chemotherapy. The device is intended to be used as a stand-alone treatment and is intended as an alternative to standard medical therapy for recurrent GBM after surgical and radiation options have been exhausted."

In September 2014, FDA approved Novocure's request for a product name change from NovoTTF-110A System to Optune®.<sup>8</sup>

In October 2015, the FDA expanded the indication for Optune® in combination with temozolomide to include newly diagnosed GBM.<sup>9</sup> The device was granted priority review status in May 2015 because there was no legally marketed alternative device available for the treatment of newly diagnosed GBM, a life-threatening condition. In July 2016, a smaller, lighter version of the Optune® device, called the Optune® System (NovoTTF-200A System), received FDA approval.

The FDA-approved label for newly diagnosed GBM reads as follows: "This device is indicated as treatment for adult patients (22 years of age or older) with histologically-confirmed glioblastoma multiforme (GBM). Optune™ with temozolomide is indicated for the treatment of adult patients

with newly diagnosed, supratentorial glioblastoma following maximal debulking surgery and completion of radiation therapy together with concomitant standard of care chemotherapy."

FDA product code: NZK.

## Rationale

### Background

#### **Glioblastoma Multiforme**

Glioblastomas, also known as glioblastoma multiforme (GBM), are the most common form of malignant primary brain tumor in adults.<sup>1</sup> GBMs are grade IV astrocytomas, a rapidly progressing and deadly type of glial cell tumor that is often resistant to standard medical therapy (e.g., bevacizumab, chemotherapy). Together, anaplastic astrocytomas and glioblastomas comprise approximately 38% of all brain and central nervous system tumors.<sup>1</sup> The peak incidence for GBM occurs between the ages of 45 and 70 years, with a median age at diagnosis of 64 years. Glioblastomas have the lowest survival rate of any central nervous system tumor; in one report, about a third of patients survived to 1 year, and the 5-year survival rate was around 5%.<sup>2</sup>

#### **Clinical Context and Therapy Purpose**

The purpose of alternating electrical field therapy, more commonly known as tumor treating fields (TTF) therapy, is to provide a treatment option that is better than existing therapies for GBM. TTF has been investigated as an adjunct to temozolomide for the treatment of newly diagnosed GBM and as an alternative or adjunct to medical therapy for progressive or recurrent GBM.

#### ***Treatment of Newly Diagnosed Glioblastoma Multiforme***

The primary treatment for patients newly diagnosed with GBM is to resect the tumor to confirm a diagnosis while debulking the tumor to relieve symptoms of increased intracranial pressure or compression. If total resection is not feasible, subtotal resection and open biopsy are options. During surgery, some patients may undergo implantation of the tumor cavity with a carmustine (bis-chloroethylnitrosourea) impregnated wafer. Due to the poor efficacy of local treatment, postsurgical treatment with adjuvant radiotherapy, chemotherapy (typically temozolomide), or a combination of these 2 therapies is recommended. After adjuvant therapy, patients may undergo maintenance therapy with temozolomide. Maintenance temozolomide is given for 5 days of every 28-day cycle for 6 cycles. Response and overall survival rates with temozolomide are higher in patients who have O<sup>6</sup>-methylguanine-DNA methyltransferase (*MGMT*) gene promoter methylation (see Blue Shield of California Medical Policy: Analysis of *MGMT* Promoter Methylation in Malignant Gliomas on *MGMT* promotor methylation for malignant gliomas).

Prognostic factors for therapy success are age, histology, performance status or physical condition of the patient, and extent of resection. National Comprehensive Cancer Network recommendations include patient age and Karnofsky Performance Status score as important determinants of postsurgical treatment choice (see the Supplemental Information section).<sup>3</sup> For patients with good performance status, the most aggressive treatment (standard radiotherapy [RT] plus temozolomide) is recommended. For patients with poor performance status, only single treatment cycles or even palliative or supportive care are recommended. Hypofractionated RT is indicated for patients with poor performance status because it is better tolerated, and more patients are able to complete RT.

Treatment of GBM is rarely curative, and tumors will recur essentially all patients.

#### ***Treatment of Recurrent Glioblastoma Multiforme***

When disease recurs, additional debulking surgery may be used if the recurrence is localized. Due to radiation tolerances, re-radiation options for patients with recurrent GBM who have previously received initial external-beam radiotherapy are limited. There is no standard adjunctive treatment for recurrent GBM. Treatment options for recurrent disease include various forms of systemic medications such as the antivascular endothelial growth factor drug

bevacizumab, alkylating agents such as nitrosoureas (e.g., lomustine, carmustine), or retreatment with temozolomide. Medical therapy is associated with side effects that include hematologic toxicity, headache, loss of appetite, nausea, vomiting, and fatigue. Response rates in recurrent disease are less than 10%, and the progression-free survival rate at 6 months is less than 20%.<sup>4</sup> There is a need for new treatments that can improve survival in patients with recurrent GBM or reduce the side effects of treatment while retaining survival benefits.

The questions addressed in this evidence review are:

- Does TTF, when used as an adjunct to maintenance medical therapy in patients with newly diagnosed GBM, improve the net health outcome?
- Does TTF, when used as an adjunct to medical therapy in patients with recurrent GBM, improve the net health outcome?
- Does TTF, when used as an alternative to medical therapy in patients with recurrent GBM, improve the net health outcome?

The following PICOTS were used to select literature to inform this review.

### ***Patients***

The relevant populations of interest are patients who have newly diagnosed GBM with good performance status or patients with recurrent GBM with good performance status. Newly diagnosed patients would have undergone initial treatment with surgery, RT, and chemotherapy and be receiving maintenance chemotherapy.

### ***Interventions***

TTF therapy is a noninvasive technology intended to treat GBM on an outpatient basis and at home using electrical fields.<sup>4-6</sup> TTF therapy exposes rapidly dividing cancer cells to electric fields of low intensity and intermediate frequency (200 kHz) that alternate in perpendicular orientation. TTF therapy is proposed to inhibit tumor growth by 2 mechanisms: the arrest of cell proliferation by causing microtubule misalignment in the mitotic spindle of rapidly dividing tumor cells and apoptosis due to movement of macromolecules and organelles during telophase.<sup>5,6</sup> Preclinical studies have indicated that the electric fields may also make the cells more susceptible to chemotherapy.

Optune (formerly NovoTTF-100A System) is the only legally marketed TTF delivery system available in the United States. The portable, battery-powered device is carried in a backpack or shoulder pack while carrying out activities of daily living. For the treatment of glioblastoma, 4 disposable transducer arrays with insulated electrodes are applied to the patient's shaved head. The transducer array layout is typically determined using specialized software. The patient's scalp is re-shaved and the transducer arrays replaced twice a week by the patient, caregiver, or device technician. The device is worn for up to 24 hours a day for the duration of treatment, except for brief periods for personal hygiene and 2 to 3 days at the end of each month. The minimum daily treatment is 18 hours. The minimum duration of treatment is 1 month, with the continuation of treatment available until recurrence.

### ***Comparators***

The following practice is currently being used to make decisions about newly diagnosed GBM: maintenance chemotherapy with temozolomide alone.

The following practices are currently being used to make decisions about recurrent GBM: medical therapy.

TTF therapy might also be compared with palliative or supportive care, where survival rarely exceeds 3 to 5 months.<sup>4</sup>

**Outcomes**

The general outcomes of interest are whether TTF improves survival or quality of life during treatment and, because most GBMs recur, the time to tumor recurrence. Measures of cognitive status and quality of life measures are also of interest to determine whether TTF alters the decline in cognition and quality of life that occur with GBM. Also, adverse events of treatment such as side effects of chemotherapy and the possibility of seizures need to be assessed.

**Timing**

Due to the rapid progression of GBM, the time of interest for both progression-free survival and overall survival is months.

**Setting**

The setting is outpatient care by an oncologist or neuro-oncologist.

**Literature Review**

Evidence reviews assess the clinical evidence to determine whether the use of a technology improves the net health outcome. Broadly defined, health outcomes are length of life, quality of life, and ability to function—including benefits and harms. Every clinical condition has specific outcomes that are important to patients and to managing the course of that condition. Validated outcome measures are necessary to ascertain whether a condition improves or worsens; and whether the magnitude of that change is clinically significant. The net health outcome is a balance of benefits and harms.

To assess whether the evidence is sufficient to draw conclusions about the net health outcome of a technology, 2 domains are examined: the relevance and the quality and credibility. To be relevant, studies must represent one or more intended clinical use of the technology in the intended population and compare an effective and appropriate alternative at a comparable intensity. For some conditions, the alternative will be supportive care or surveillance. The quality and credibility of the evidence depend on study design and conduct, minimizing bias and confounding that can generate incorrect findings. The randomized controlled trial (RCT) is preferred to assess efficacy; however, in some circumstances, nonrandomized studies may be adequate. RCTs are rarely large enough or long enough to capture less common adverse events and long-term effects. Other types of studies can be used for these purposes and to assess generalizability to broader clinical populations and settings of clinical practice.

For this review, 3 indications are evaluated: (1) tumor treating fields (TTF) as an adjunct to maintenance chemotherapy in newly diagnosed patients following initial treatment with surgery, radiotherapy and chemotherapy and (2) TTF as an adjunct or (3) alternative to medical therapy (e.g., bevacizumab, chemotherapy) in progressive or recurrent glioblastoma multiforme (GBM).

**Study Selection**

The PICOTS was used to select relevant studies.

- To assess efficacy outcomes, comparative controlled prospective trials were sought, with a preference for RCTs.
- To assess longer term outcomes and adverse events, single-arm studies that capture longer periods of follow-up and/or larger populations were sought.
- Within each category of study design, studies with larger sample size studies and longer duration were sought.

**TTF Therapy as an Adjunct to Standard Maintenance Care for Newly Diagnosed GBM  
Randomized Controlled Trials**

Stupp et al (2017) published results of the EF-14 multicenter, open-label phase 3 RCT that evaluated maintenance therapy with TTF for newly diagnosed GBM.<sup>10</sup> The trial included 695 patients from 83 sites who had supratentorial GBM and had completed standard treatment consisting of biopsy or surgical resection followed by radiotherapy and chemotherapy (see Table 1). A Karnofsky Performance Status (KPS) score of 70 or higher was an additional inclusion

criterion to ensure independence in activities of daily living, and patients with rapidly progressing GBM following radiochemotherapy were excluded from the trial. Patients were randomized in a 2:1 fashion to TTF plus maintenance temozolomide or maintenance temozolomide alone.

All patients were seen monthly for follow-up. Quality of life (QOL) was assessed every 3 months, and magnetic resonance imaging (MRI) was performed every 2 months until tumor progression. Tumor progression on MRI was adjudicated by a central review committee blinded to treatment group. The primary outcome was progression-free survival (PFS), and the secondary outcome was overall survival (OS). The analysis was by intention-to-treat, including 26 patients from the control arm who crossed over to TTF following the planned interim analysis.

In 2014, an independent data and safety monitoring board concluded from the planned interim analysis that the trial met its predefined boundaries for success (improvement in PFS and OS) and recommended trial termination. The Food and Drug Administration approved the trial termination, and the trial was closed to recruitment with 695 of the planned 700 participants randomized. Control arm participants were allowed to cross over to the experimental treatment at this time. The interim analysis, which the Food and Drug Administration considered for the 2015 expanded approval of Optune, was published by Stupp et al (2015).<sup>11</sup> At the time of the interim analysis, data were available for 210 patients randomized to TTF plus temozolomide and 105 patients to temozolomide alone. Follow-up of the remainder of the 695 enrolled patients continued after enrollment was closed.

**Table 1. Key Randomized Controlled Trial Characteristics for Newly Diagnosed Glioblastoma**

Study; Trial	Countries	Sites	Dates	Participants	Interventions	
					Active	Comparator
Stupp et al (2017) <sup>10</sup> ; EF-14	U.S., E.U., South Korea, Israel	83	2009-2016	<ul style="list-style-type: none"> <li>695 newly diagnosed with GBM and treated by radiochemotherapy</li> <li>KPS score <math>\geq 70</math></li> </ul>	TTF >18 h/d plus maintenance temozolomide (n=466)	Maintenance temozolomide alone (5 d every 28 d for 6 cycles) (n=229)

GBM: glioblastoma multiforme; h/d; hours per day; KPS: Karnofsky Performance Status; TTF: tumor treatment fields.

Results of the final analysis of the EF-14 trial were similar to the interim analysis and are shown in Table 2. Both PFS and OS improved with the addition of TTF therapy to standard maintenance chemotherapy (i.e., temozolomide). PFS increased by 2.7 mo ( $p < 0.001$ ) and OS increased by 4.9 mo ( $p < 0.001$ ) in the TTF group. The time to a decrease in mental function was 2.5 months longer with TTF therapy ( $p < 0.01$ ).

There was a similar percentage of dropouts at the final analysis—with 49 (11%) patients in the TTF group and 27 (12%) patients in the temozolomide alone group. More treatment cycles with temozolomide were administered in the TTF group (median, 6 for TTF group vs 5 for controls), a finding that is consistent with the longer PFS. Rates of adverse events were similar between the groups, including rates of seizures. In secondary analysis of patients who had not progressed, there was no reduction in health-related quality of life with TTF compared with temozolomide alone aside from “itchy skin”.<sup>12</sup> Interpretation of this result is limited by the low percentage of patients who completed the health-related quality of life assessments at follow-up (65.8% of the 655 patients alive at 3 months and 41.7% of the 473 patients alive at 12 months). A mixed-model analysis, which accounts for missing data, confirmed the results of the mean change from baseline analysis.

**Table 2. Key Randomized Controlled Trial Results for Newly Diagnosed Glioblastoma**

Study	Final N (%)	Median PFS (95% CI), mo	Median OS (95% CI), mo	Systemic Adverse Events, n (%)	Seizures, n (%)	Time to 6-Point Decline in MMSE Score (95% CI), mo
Stupp et al (2017) <sup>10</sup>						
TTF + temozolomide	417 (89)	6.7 (6.1 to 8.1)	20.9 (19.3 to 22.7)	218 (48)	26 (6)	16.7 (14.7 to 19.0)
Temozolomide alone	202 (88)	4.0 (3.8 to 4.4)	16.0 (14.0 to 18.4)	94 (44)	13 (6)	14.2 (12.7 to 17.0)
HR (95% CI)		0.63 (0.52 to 0.76)	0.63 (0.53 to 0.76)			0.79 (0.66 to 0.95)
P value		<0.001	<0.001	0.58		0.01

CI: confidence interval; HR: hazard ratio; MMSE: Mini-Mental State Examination; OS: overall survival; PFS: progression-free survival; TTF: tumor treatment fields.

Tables 3 and 4 display notable gaps identified in this trial, the major limitation is the lack of patient blinding to treatment assignment. However, PFS was assessed by investigators who were blinded to treatment and placebo effects on OS were expected to be minimal. Investigators considered it practically unfeasible (due to the heat and current of the TTF therapy) and ethically unacceptable to submit the control patients to repeated shaving of the head and continuous wear of a sham device over many months.

### Section Summary: TTF Therapy as an Adjunct to Standard Maintenance Care for Newly Diagnosed GBM

The final analysis of the EF-14 trial, which included 695 patients from 83 sites, found a statistically and clinically significant increase of 2.7 months in PFS and an increase of 4.9 months in OS with the addition of TTF therapy to standard maintenance therapy (i.e., temozolomide) in patients with newly diagnosed GBM. There was no sham control, and patients were not blinded to treatment assignment, but PFS was assessed by blinded evaluators, and placebo effects on the objective measure of OS were likely to be minimal. There was no evidence of a negative impact of TTF therapy on health-related quality of life, except for itchy skin from the transducers.

### TTF Therapy as an Adjunct or Alternative to Medical Therapy for Progressive or Recurrent GBM Randomized Controlled Trials

The 2011 Food and Drug Administration approval of the NovoTTF-100A System (now called Optune) was based on a phase 3 multinational RCT (EF-11), results of which were published by Stupp et al (2012).<sup>4</sup> This trial compared TTF therapy alone with physician's choice medical therapy in 237 adults who had relapsed or progressive glioblastoma (see Table 5). Patients had failed conventional treatment with radiotherapy, chemotherapy, and/or surgery, and more than 80% of participants had failed 2 or more prior chemotherapy regimens. In this trial, the term chemotherapy also applied to targeted agents such as bevacizumab. Patient characteristics and performance of additional post-recurrence debulking surgery were similar in the 2 groups.

**Table 5. Summary of Key Randomized Controlled Trial Characteristics for Progressive or Recurrent Glioblastoma**

Study; Trial	Countries	Sites	Dates	Participants	Interventions	
					Active	Comparator
Stupp et al (2012) <sup>4</sup> ; EF-11	U.S., E.U., Israel	28	1987-2013	<ul style="list-style-type: none"> <li>237 adults with relapsed or progressive supratentorial glioblastoma</li> <li>KPS score <math>\geq 70\%</math></li> </ul>	120 patients treated with TTF alone, 93 (78%) completed 1 cycle	117 patients treated with physician's choice of medical therapy <sup>a</sup>

EU: European Union; KPS: Karnofsky Performance Status; TTF: tumor treating fields.

<sup>a</sup> Medical therapy included bevacizumab, irinotecan, nitrosoureas, platinum-based chemotherapy (i.e., carboplatin); temozolomide; or a combination of procarbazine, chloroethyl ether, and vincristine.

Participants were followed monthly, including laboratory tests. MRI images were evaluated at 2, 4, and 6 months from initiation of treatment, with subsequent MRIs performed according to local practice until disease progression. QOL questionnaires were completed every 3 months. Medical follow-up continued for 2 months after disease progression. Monthly telephone interviews with participants' caregivers were used to assess mortality rates. The primary end point was OS. Secondary end points included PFS, the percentage of patients with PFS at 6 months, time to progression, 1-year survival rate, QOL, and radiologic response. All end points were evaluated using intention-to-treat analysis.

The trial did not reach its primary end point of improved survival compared with active medical therapy (see Table 6). With a median follow-up of 39 months, 93% of patients had died. There was not a statistically significant difference in survival rates at 1, 2, and 3 years between groups. Patients in the TTF group did not, however, suffer the typical systemic side effects of chemotherapy. The most common adverse event in the TTF group was grade 1 and 2 contact dermatitis on the scalp, which resolved with topical corticosteroids and did not require treatment breaks. Control participants experienced grade 2, 3, or 4 events by organ system related to the pharmacologic activity of chemotherapy agents used. Hematologic events of

grade 2 or greater were observed in 17% of chemotherapy patients compared with 3% of TTF patients. Gastrointestinal disorders of grade 2 or greater were identified in 17% of chemotherapy patients compared with 4% of TTF patients. Severe (grades 3-4) hematologic and gastrointestinal toxicity was observed in 7% of chemotherapy controls compared with 1% of the TTF group.

Longitudinal QOL data, available in 63 (27%) participants, showed no meaningful differences between groups for the domains of global health and social functioning. However, cognitive and emotional functioning domains favored TTF therapy. Symptom scale analysis was by treatment-associated toxicity; appetite loss, diarrhea, constipation, nausea, and vomiting were directly related to the chemotherapy administration.

The trial had a number of limitations (see Tables 7 and 8), that included lack of blinding and high loss to follow-up. Discontinuation of TTF therapy occurred in 22% of patients due to noncompliance or inability to handle the device, usually within the first few days. In the control group, 21 (18%) patients did not return to the treatment site, and details on disease progression and toxicity were not available. Longitudinal QOL could be analyzed only for 27% of patients who remained on study therapy for 3 months. The trial was designed as a superiority trial and did not provide adequate evidence of noninferiority.

### Nonrandomized Comparative Studies

Kesari et al (2017) conducted a post hoc analysis of the EF-14 trial (see Stupp et al [2017] above) to evaluate the efficacy of TTF in patients who had the first recurrence.<sup>13</sup> Some patients in the temozolomide alone group crossed over to receive TTF plus chemotherapy after the first recurrence, resulting in 144 patients who received TTF fields plus chemotherapy and 60 patients who received chemotherapy alone for recurrent GBM (see Table 9). Patient characteristics and second-line treatments were well-balanced between the groups, with bevacizumab the most common second-line therapy. The median OS in patients treated with systemic therapy alone was 9.2 months (see Table 10). In comparison, the group of patients who received TTF therapy in addition to systemic therapy had a median OS of 11.8 months (p=0.043).

A registry study published Mrugala et al (2014) assessed OS data from patients who received NovoTTF therapy in a real-world, clinical practice setting (see Table 9).<sup>14</sup> Concurrent treatment was not captured in the registry, and it is possible that some patients received combination therapy. Median OS in the PRiDe clinical practice dataset (9.6 mo) was reported as superior to that attained in the EF-11 pivotal trial (6.6 mo, p<0.001) (see Table 10). More patients in the PRiDe registry were treated for first recurrence (33% vs 9%), and more had received bevacizumab as prior therapy (55% vs 19%). The PRiDe investigators reported no novel or unexpected treatment-related adverse events compared with the EF-11 trial.

**Table 9. Characteristics of Key Nonrandomized Trial Results**

Post hoc analyses of the EF-11 pivotal trial have been reported. Wong et al (2014) published a subgroup analysis to determine characteristics of responders and nonresponders in the active treatment and active treatment control.<sup>15</sup> They found that responders had a lower grade of histology and lower daily dexamethasone use than nonresponders. A second post hoc analysis by Kanner et al (2014) of the EF-11 pivotal trial data was performed to evaluate OS among patients who finished at least 1 complete course of TTF or chemotherapy.<sup>16</sup> The investigators reported that median OS was 7.7 months in the TTF group compared with 5.9 months in the chemotherapy group ( $p=0.009$ ). These post hoc analyses are considered to be hypothesis-generating.

#### **Section Summary: TTF Therapy as an Adjunct or Alternative to Chemotherapy for Progressive or Recurrent GBM**

The single RCT for TTF as an alternative to chemotherapy reported that outcomes following TTF therapy were similar to outcomes following standard chemotherapy. However, this RCT is not sufficient to permit conclusions on the efficacy of the device. The noninferiority of TTF compared with chemotherapy might be considered a sufficient health benefit, if TTF reduced treatment toxicity. However, because the trial was not designed as a noninferiority trial no inferences of noninferiority compared with chemotherapy can be made. Physician's choice therapy during the trial was heterogenous, although analysis indicated that survival was not affected by choice of chemotherapy. More patients in the TTF group than in the control group did not complete the treatment course. The number of patients who contributed QOL data was approximately one-quarter of total enrollment, and the self-reported QOL indicators might have been subject to bias due to the lack of blinding.

A nonrandomized post hoc evaluation of the EF-14 trial suggests that TTF may improve survival when combined with chemotherapy for recurrent GBM. This analysis should be considered hypothesis-generating, and further study in high-quality RCTs is needed.

#### **Summary of Evidence**

For individuals who have newly diagnosed GBM on maintenance therapy after initial treatment who receive TTF therapy as an adjunct to standard maintenance therapy, the evidence includes an RCT. Relevant outcomes include overall survival, disease-specific survival, symptoms, functional outcomes, quality of life, and treatment-related morbidity. The EF-14 trial found a significant increase of 2.7 months in progression-free survival and an increase of 4.9 months in overall survival with the addition of TTF therapy to standard maintenance therapy (i.e., temozolomide) in patients with newly diagnosed GBM. Although patients were not blinded to treatment assignment, progression-free survival was assessed by blinded evaluators, and the placebo effects on the objective measure of overall survival are expected to be minimal. This technology represents a clinically significant option in the treatment of patients with GBM, for whom options are limited. The evidence is sufficient to determine that the technology results in a meaningful improvement in the net health outcome.

For individuals who have progressive or recurrent GBM who receive TTF therapy as an adjunct or alternative to standard medical therapy, the evidence includes an RCT and nonrandomized comparative studies. Relevant outcomes are overall survival, disease-specific survival, quality of life, and treatment-related morbidity. The single RCT evaluating TTF therapy for recurrent GBM did not show superiority of TTF therapy for the primary outcome (overall survival) compared with physicians' choice chemotherapy. Because no serious adverse effects have been identified with TTF therapy, this raises the possibility that treatment with TTF might reduce the toxicity associated with treatment for recurrent GBM. A reduction in chemotherapy-associated toxicity without loss of efficacy would be considered a net health benefit. However, this RCT is not sufficient to permit conclusions on the efficacy of the device. Because the trial was not designed as a noninferiority trial, no inferences of noninferiority compared with chemotherapy can be made. Also, quality of life assessment was measured in an insufficient number of patients to reach firm conclusions on differences in quality of life between TTF therapy and medical treatment. The highest quality study of TTF combined with medical treatment for recurrent GBM is a post hoc analysis of the EF-14 trial. A high-quality, prospective RCT is needed. The evidence is insufficient to determine the effects of the technology on health outcomes.

### Supplemental Information

#### Clinical Input From Physician Specialty Societies and Academic Medical Centers

While the various physician specialty societies and academic medical centers may collaborate with and make recommendations during this process, through the provision of appropriate reviewers, input received does not represent an endorsement or position statement by the physician specialty societies or academic medical centers, unless otherwise noted.

In response to requests from Blue Cross Blue Shield Association, input was received from 3 physician specialty societies (one of which provided 6 responses and 2 of which provided 1 response each) and 1 academic medical center (total of 9 individual responses) in 2016. There was majority support, but not consensus, for the use of tumor treatment fields therapy as an adjunct to maintenance treatment following initial therapy for glioblastoma multiforme. There was mixed support for the use of tumor treatment fields as an alternative to chemotherapy in advanced or recurrent glioblastoma multiforme.

#### Practice Guidelines and Position Statements

National Comprehensive Cancer Network guidelines on central nervous system cancers (v.1.2018) include recommendations for the treatment of glioblastoma (see Table 11).<sup>3</sup> For the initial treatment of patients with glioblastoma with good performance status and either methylated or unmethylated or indeterminate O<sup>6</sup>-methylguanine-DNA methyltransferase promotor status, treatment with standard brain radiotherapy plus concurrent temozolomide and adjuvant temozolomide plus alternating electric field therapy is a category 1 recommendation. Alternating electric currents therapy is only an option for patients with supratentorial disease. Consideration of alternating electric field therapy for recurrent glioblastoma is a category 2B recommendation.

**Table 11. Guidelines for Adjuvant Treatment of Glioblastoma, by Age and Performance Status**

Age, y	KPS Score,%	Treatment Options	Category
≤70	≥60	<ul style="list-style-type: none"> <li>• Standard RT plus concurrent and adjuvant temozolomide plus TTF</li> <li>• Standard RT plus concurrent and adjuvant temozolomide</li> </ul>	1
≤70	<60	<ul style="list-style-type: none"> <li>• Hypofractionated RT with/without concurrent or adjuvant temozolomide</li> <li>• Temozolomide</li> <li>• Palliative/best supportive care</li> </ul>	2A

Age, y	KPS Score,%	Treatment Options	Category
		• Palliative/best supportive care	

KPS: Karnofsky Performance Status; RT: radiotherapy; TTF: tumor treating fields.

#### U.S. Preventive Services Task Force Recommendations

Not applicable.

#### Medicare National Coverage

There is no national coverage determination. In the absence of a national coverage determination, coverage decisions are left to the discretion of local Medicare carriers.

#### Ongoing and Unpublished Clinical Trials

Some currently unpublished trials that might influence this review are listed in Table 12. Of particular note are the phase 3 trials evaluating TTF therapy in non-small-cell lung cancer and pancreatic cancer. TTF therapy is an active area of research for mechanisms underlying its effects on cancer cells.

**Table 12. Summary of Key Trials**

NCT No.	Trial Name	Planned Enrollment	Completion Date
<b>Ongoing</b>			
NCT01971281 <sup>a</sup>	A Phase II Study of TTFields (150 kHz) Concomitant With Gemcitabine and TTFields Concomitant With Gemcitabine Plus Nab-paclitaxel for Front-line Therapy of Advanced Pancreatic Adenocarcinoma	40	Dec 2017 (ongoing)
NCT01894061 <sup>a</sup>	A Prospective Phase II Trial of NovoTTF-100A With Bevacizumab (Avastin) in Patients With Recurrent Glioblastoma	40	Dec 2018
NCT02663271 <sup>a</sup>	A Phase 2, Multi-center, Single Arm, Histologically Controlled Study Testing the Combination of TTFields and Pulsed Bevacizumab Treatment in Patients With Bevacizumab-refractory Recurrent Glioblastoma	18	Mar 2019
NCT02831959 <sup>a</sup>	Pivotal, Open-label, Randomized Study of Radiosurgery With or Without Tumor Treating Fields (TTFields) (150kHz) for 1-10 Brain Metastases From Non-small Cell Lung Cancer (NSCLC) (METIS)	270	Jul 2019
NCT02973789 <sup>a</sup>	LUNAR: Pivotal, Randomized, Open-label Study of Tumor Treating Fields (TTFields) Concurrent With Standard of Care Therapies for Treatment of Stage 4 Non-small Cell Lung Cancer (NSCLC) Following Platinum Failure	534	Dec 2021
NCT02743078 <sup>a</sup>	Phase II Trial Of Optune® Plus Bevacizumab In Bevacizumab-Refractory Recurrent Glioblastoma	85	Aug 2022
NCT03377491 <sup>a</sup>	EF-27 Pivotal, Randomized, Open-label Study of Tumor Treating Fields (TTFields, 150kHz) Concomitant With Gemcitabine and Nab-paclitaxel for Front-line Treatment of Locally-advanced Pancreatic Adenocarcinoma (PANOVA-3)	556	Dec 2022

NCT: national clinical trial.

<sup>a</sup> Denotes industry-sponsored or cosponsored trial.

## Documentation for Clinical Review

Please provide the following documentation (if/when requested):

- History and physical and/or consultation notes including:
  - Clinical findings (i.e., pertinent symptoms and duration)
  - Karnofsky Performance Score
  - Past and present diagnostic testing and results

- Previous treatment plan and response
- Tumor type and description
- Documentation of the patient's understanding on the use of the device
- Radiology report(s) and interpretation (i.e., MRI, CT scan, PET)

**Post Service**

- Results/reports of test performed

**Coding**

*This Policy relates only to the services or supplies described herein. Benefits may vary according to product design; therefore, contract language should be reviewed before applying the terms of the Policy. Inclusion or exclusion of codes does not constitute or imply member coverage or provider reimbursement.*

**MN/IE**

The following services may be considered medically necessary in certain instances and investigational in others. Services may be considered medically necessary when policy criteria are met. Services may be considered investigational when the policy criteria are not met or when the code describes application of a product in the position statement that is investigational.

Type	Code	Description
CPT®	None	
HCPCS	A4555	Electrode/transducer for use with electrical stimulation device used for cancer treatment, replacement only
	E0766	Electrical stimulation device used for cancer treatment, includes all accessories, any type
ICD-10 Procedure	None	

**Policy History**

This section provides a chronological history of the activities, updates and changes that have occurred with this Medical Policy.

Effective Date	Action	Reason
10/31/2014	BCBSA Medical Policy adoption	Medical Policy Committee
05/01/2016	Policy revision without position change	Medical Policy Committee
10/01/2016	Policy revision without position change	Medical Policy Committee
09/01/2017	Policy revision without position change	Medical Policy Committee
11/01/2018	Policy title change from Tumor Treatment Fields Therapy for Glioblastoma Policy revision with position change	Medical Policy Committee

**Definitions of Decision Determinations**

**Medically Necessary:** A treatment, procedure, or drug is medically necessary only when it has been established as safe and effective for the particular symptoms or diagnosis, is not investigational or experimental, is not being provided primarily for the convenience of the patient or the provider, and is provided at the most appropriate level to treat the condition.

**Investigational/Experimental:** A treatment, procedure, or drug is investigational when it has not been recognized as safe and effective for use in treating the particular condition in accordance

with generally accepted professional medical standards. This includes services where approval by the federal or state governmental is required prior to use, but has not yet been granted.

**Split Evaluation:** Blue Shield of California/Blue Shield of California Life & Health Insurance Company (Blue Shield) policy review can result in a split evaluation, where a treatment, procedure, or drug will be considered to be investigational for certain indications or conditions, but will be deemed safe and effective for other indications or conditions, and therefore potentially medically necessary in those instances.

#### **Prior Authorization Requirements (as applicable to your plan)**

Within five days before the actual date of service, the provider must confirm with Blue Shield that the member's health plan coverage is still in effect. Blue Shield reserves the right to revoke an authorization prior to services being rendered based on cancellation of the member's eligibility. Final determination of benefits will be made after review of the claim for limitations or exclusions.

Questions regarding the applicability of this policy should be directed to the Prior Authorization Department. Please call (800) 541-6652 or visit the provider portal at [www.blueshieldca.com/provider](http://www.blueshieldca.com/provider).

*Disclaimer: This medical policy is a guide in evaluating the medical necessity of a particular service or treatment. Blue Shield of California may consider published peer-reviewed scientific literature, national guidelines, and local standards of practice in developing its medical policy. Federal and state law, as well as contract language, including definitions and specific contract provisions/exclusions, take precedence over medical policy and must be considered first in determining covered services. Member contracts may differ in their benefits. Blue Shield reserves the right to review and update policies as appropriate.*

### Medical Policy

#### 2.03.014 Electric Tumor Treatment Fields

Original MPC Approval: 04/05/2013

Last Review: 03/19/2018

Last Revision: 05/21/2018

#### Description

Glioblastoma multiforme (GBM) is the most common malignant primary intracranial tumor, with a median survival of only 10-14 months. Only 3% to 5% of patients survive more than 3 years. Recurrence is extremely common, which further decreases survival to 5-7 months. GBM is an aggressive tumor that presents treatment challenges owing to the resistance of the tumor cells to conventional therapies and the susceptibility of the brain to damage.

Electric tumor treatment fields (TTF) are low-intensity, intermediate frequency (100-200 kHz) alternating electric fields currently being explored as a possible method of improving survival in patients with GBM. The device consists of a portable electric field generator, a pair of electrodes, and accessories. The electrodes are placed on the patient's shaved scalp and current is applied at the prescribed frequency. The belief is that alternating electrical fields disrupt the rapidly dividing cancer cells, dislocating intracellular structures and leading to tumor cell death. Healthy brain tissue is not appreciably affected by the electrical current.

#### Policy

Electric tumor treating fields (TTF) is considered **medically necessary** for the treatment of histologically-confirmed glioblastoma (GBM) in patients 18 years of age and older.

Electric tumor treating fields (TTF) is considered **medically necessary** for patients that have completed debulking surgery or biopsy.

Electric tumor treating fields (TTF) is considered **medically necessary** for patients that have completed chemotherapy therapy and radiation therapy.

Electric tumor treating fields (TTF) is considered **medically necessary** when used concurrent with temozolomide (TMZ) for the treatment of GBM.

Electric tumor treating fields (TTF) is considered **experimental / investigational** for the treatment of any conditions not outlined above.

#### Policy Guidelines

1. The technology must have final approval from the appropriate government regulatory bodies:

The NovoTTF-100A system (Novocure, Ltd.) received a premarket approval (PMA) from the FDA in April 2011. According to the FDA approval document, "The NovoTTF-100A System is intended as a treatment for adult patients (22 years of age or older) with histologically confirmed glioblastoma multiforme (GBM), following histologically- or radiologically-confirmed recurrence in the supratentorial region of the brain after receiving chemotherapy. The device is intended to be used as a monotherapy, and is intended as an alternative to standard medical therapy for GBM after surgical and radiation options have been exhausted."

2. The scientific evidence must permit conclusions concerning the effect on health outcomes:

Pilot-level studies published since 2007 have shown mixed results. Overall when the primary end-point is taken to cancer survival the TTF treatment is similar to active chemotherapy, but quality of life analysis tends to favor the TTF treatment.

3. The technology must improve the net health outcome:

TTF therapy is still considered a novel treatment method, but with a high safety profile. The published evidence is not sufficient to determine net health outcomes.

4. The technology must be as effective as any established alternatives:

In terms of cancer survival, the evidence has not established that TTF treatment is at least as effective as the standard protocol.

5. The improvement must be attainable outside the investigational settings:

It is not known whether improvement can be expected outside of the investigational setting.

#### Update 2015:

A search of the peer-reviewed literature was performed for the period of March 2013 through October 2015. The NovoTTF-100A system's name was changed to Optune on September 28, 2014, based on a supplemental approval to the original PMA from the FDA. The newly approved, expanded FDA indications for the Optune is for treatment of adult patients (22 years of age or older) with histologically-confirmed glioblastoma multiforme (GBM). Optune with temozolomide is intended for the treatment of adult patients with newly diagnosed, supratentorial glioblastoma following maximal debulking surgery and completion of radiation therapy together with concomitant standard of care chemotherapy.

Electric tumor treatment fields for the treatment of GBM and other solid tumors continue to be evaluated in clinical trials. The policy statement is unchanged.

#### Update 2018:

A search of the peer-reviewed literature was performed for the period of November 2015 through January 2018. In 2015, Stupp et al published results of a randomized controlled trial (RCT) that evaluated both safety and efficacy of tumor-treating field (TTF) used in combination with temozolomide maintenance treatment after chemoradiation therapy for patients with glioblastoma multiforme (GBM). 695 patients were randomized in a 2:1 fashion to either receive maintenance treatment with TTF with temozolomide (TMZ) (n=466) or TMZ alone (n=229). Study eligibility required patients to be 18 years or older, have a histologically confirmed supratentorial glioblastoma, be progression-free after having undergone maximal safe debulking surgery when feasible or biopsy, and have completed standard concomitant chemoradiotherapy with TMZ. The median time from diagnosis to randomization was 3.8 months in both groups and patients were not blinded due to ethical concerns. TTF was delivered continuously (> 18 hours/day) via 4 transducers placed on the shaved scalp and TMZ (150-200 mg/m<sup>2</sup>/d) was given for 5 days of each 28-day cycle. Transducer array layouts were determined using the NvoTAL mapping software system for TTF fields to optimize field intensity within the treated tumor. A planned interim analysis was to be conducted on the first 315 patients at 18 months follow-up. The primary study endpoint was progression-free survival (PFS) in the intent-to-treat populations (with a significance threshold of p≤0.01) with overall survival (OS) in the per-protocol population (n = 280) as a powered secondary end point (significance threshold of .006). A total of 695 4 – DME85 patients were enrolled across 83 centers; however, the trial was terminated as it met its efficacy endpoints at interim analysis (median 38 months, 315 patients). The interim analysis included the planned 315 subjects, with 210 in the TTF/TMZ group and 105 in the TMZ only group. The analysis was conducted at a median 38 months follow-up (range, 18-60 months). Prespecified per-protocol median PFS in the TTF/TMZ group was 7.1 months (95% CI, 5.9- 8.2 months) compared to 4 months (95% CI, 3.3-5.2 months) in the TMZ only group (hazard ratio (HR), 0.62 [98.7% CI, 0.43-0.89]; P = .001). The median OS in the per-protocol population was statistically improved in the TTF/TMZ group (20.5 months; 95% CI, 16.7-25.0 months) compared to the TMZ only group (15.6 months; 95% CI, 13.3-19.1 months; HR, 0.64 [99.4% CI, 0.42-0.98]; P = .004). An additional analysis of the intention-to-treat population demonstrated and OS of 19.6 months (95% CI, 16.6-24.4 months) in the TTF/TMZ group compared to 16.6 months (95%CI, 13.6- 19.2months) in the TMZ only group (HR,0.74 [95% CI,0.56-0.98]; stratified log-rank p = .03). Forty-three percent of patients in the TTF/TMZ group were alive at 2-year follow-up, compared to 29% in the TMZ only group (p = .006).

The results of this study demonstrate an approximate three-month improvement of PFS and five-month improvement of OS when TTF therapy is used concurrently with TMZ in patients with newly diagnosed GBM.

## **Benefit Applications**

**Electric tumor treatment fields (TTF) services must be preauthorized for HMO members only.** Providers should submit preauthorization requests online at <https://provider.carefirst.com> or call 1-866-773-2884 (1-866-PRE-AUTH).

**Check the member's contract for benefits.**

NOTE: For FEP business, check the member's contract for benefits.

## Clinical Policy: Electric Tumor Treating Fields (Optune)

Reference Number: CP.MP.145

Last Review Date: 03/18

[Coding Implications](#)

[Revision Log](#)

See [Important Reminder](#) at the end of this policy for important regulatory and legal information.

### Description

Electric tumor treating fields (TTF), also known as alternating electric field therapy, are used for the treatment of glioblastoma, and are delivered by Optune<sup>®</sup> (NovoCure<sup>™</sup>), a portable medical device that generates low-intensity electric fields termed Tumor Treating Fields. TTF are believed to disrupt the rapid cell division exhibited by cancer cells, with the alternating electrical fields applied to the brain through electrodes placed on the scalp. The device is worn by the patient throughout the day and attached to the head by electrodes which creates a low intensity, alternating electric field within the tumor that exerts physical forces on electrically charged cellular components, preventing the normal mitotic process and causing cancer cell death prior to division.

### Policy/Criteria

- I. It is the policy of health plans affiliated with Centene Corporation<sup>®</sup> that TTF therapy is **medically necessary** for the following indication:
  - A. New diagnosis of glioblastoma, histologically confirmed, and all of the following:
    1. Glioblastoma is in the supratentorial region;
    2. Member has good performance status, as defined by a Karnofsky Performance Status rating of  $\geq 60$ ;
    3. Alternating electric field therapy will be delivered in conjunction with temozolomide after standard surgical and radiation therapies have been completed.
  - B. Recurrent glioblastoma, histologically- or radiologically- confirmed and all of the following:
    1. Glioblastoma is in the supratentorial region;
    2. Alternating electric field therapy will be used as a monotherapy, after standard treatment with surgery, radiation, and chemotherapy.
- II. It is the policy of health plans affiliated with Centene Corporation<sup>®</sup> that TTF therapy is **investigational and not medically necessary** for all other indications.
- III. It is the policy of health plans affiliated with Centene Corporation<sup>®</sup> that computer mapping software (NovoTal<sup>™</sup>) for planning TTF therapy is **investigational and not medically necessary** for all indications, as there is insufficient evidence to establish the efficacy of these products in the long-term outcomes of patients receiving TTF therapy.

### Background

#### *Optune Product Description<sup>1</sup>*

Optune, formerly NovoTTF-100A produces alternating electrical fields within the human body that disrupt the rapid cell division exhibited by cancer cells, with the alternating electrical fields applied to the brain through transducer arrays placed on the scalp. Electric TTF alter the tumor cell polarity at an intermediate frequency (on the order of 100-300 kHz). The frequency used for

a particular treatment is specific to the cell type being treated (e.g., 200kHz for GBM). In contrast, the TTF have not been shown to have an effect on cells that are not undergoing division. Since most normal adult brain cells proliferate very slowly, if at all, they are hypothesized to be little affected by the TTF. Testing demonstrates no differences between treated and control animals in histology of the major internal organs (including the brain), blood examination, cardiac rhythm, body temperature, or in animal behavior. In addition, because the fields alternate so rapidly, they have no effect on normal quiescent cells nor do they stimulate nerves and muscles. It is noted that, because TTF are only applied to the brain, they have no effect on rapidly proliferating cells in the rest of the body. The intensities of the electric fields within the tissues are very small and do not result in any meaningful increase in tissue temperature. Thus, TTF application has the advantage of being highly selective and is not expected to be associated with significant toxicity.

#### *Position Statement*

Guidelines from the National Comprehensive Cancer Network (NCCN) on central nervous system cancers, recommend alternating electrical fields therapy as a treatment option for newly diagnosed glioblastoma (2A- uniform consensus, based on low-quality evidence). The NCCN guidelines state TTF is recommended “for patients with good performance status and either methylated or unmethylated/indeterminate MGMT promoter status,” in conjunction with standard brain radiation therapy plus concurrent temozolomide and adjuvant temozolomide.<sup>2</sup> For recurrent glioblastoma, NCCN gives alternating electrical field therapy a 2B rating (consensus based on low-quality evidence).<sup>2</sup>

#### *Evidence for Optune*

Initial FDA approval for recurrent glioblastoma was based on Stupp et al.’s 2012<sup>3</sup> phase III clinical trial that randomized 237 patients to chemotherapy-free treatment of NovoTTF (20-24h/day) versus active chemotherapy in the treatment of patients with recurrent glioblastoma<sup>5</sup>. Primary end-point was improvement of overall survival. Patients were randomized to TTF alone or active chemotherapy control. Responses were more common in the TTF arm (14% versus 9.6%, p=0.19) and TTF-related adverse events were mild. Quality of life analyses favored TTF therapy in most domains. The investigators concluded that no improvement in overall survival was demonstrated. However, efficacy and activity with this chemotherapy-free treatment device appears comparable to chemotherapy regimens that are commonly used for recurrent glioblastoma. Toxicity and quality of life measures favored TTF.

The FDA based its approval<sup>4</sup> of the newly diagnosed glioblastoma indication of the Optune device on results from a 2015 clinical trial by Stupp et al.<sup>5</sup>. The EF-14 trial included 695 patients newly diagnosed with GB, and compared those who used Optune with temozolomide to those receiving temozolomide alone. Patients who used the device along with temozolomide lived, on average, about seven months with no disease progression compared to four months for those who had the drug alone. The Optune plus temozolomide group survived for an average of 19.4 months after starting treatment compared to 16.6 months for those who were treated with only temozolomide<sup>5</sup>. One critique of this study is that the study was terminated at the pre-planned intermediate analysis due to success of the TTF treatment. With the newly diagnosed glioblastoma indication, Optune can be used for GBM before the disease progresses. For newly

diagnosed GBM, Optune is not intended to be used as a substitute for standard treatments, but rather as an adjunct therapy, and should not be used without a physician's supervision.

Hayes conducted a review of the available literature on TTF, noting that overall the body of evidence was of fair to very poor quality, although it was consistently positive.<sup>6</sup> Hayes found the evidence to be stronger for the use of TTF for recurrent disease as opposed to newly diagnosed disease, as there were more supportive studies for recurrent disease at the time of publication (2 vs. 6). Out of the 10 studies they reviewed, pertaining to the use of TTF in patients with GBM and select other cancers, two were of fair quality, and the other eight ranged from poor quality to very poor quality. The two fair quality trials were those conducted by Stupp et al. in 2012<sup>5</sup> and 2015<sup>4</sup>, although these were noted to have limitations such as lack of a sham intervention and significant loss to follow up (22% and 20%, respectively)<sup>6</sup>.

A post-hoc analysis of Stupp et al.'s E-14 trial of TTF plus temozolomide versus temozolomide alone in newly diagnosed glioblastoma compared the efficacy of TTF plus physician's choice of chemotherapy versus chemotherapy alone after first recurrence<sup>7</sup>. Median overall survival in the TTF plus chemotherapy was 11.8 months versus 9.2 months for the chemotherapy only group ( $p=.049$ )<sup>7</sup>. TTF demonstrated low toxicity, consistent with previous studies. Limitations of this analysis are its post-hoc nature, as well as the crossover of 13 patients from the temozolomide only group to the TTF plus chemo group after approval and commercial availability of TTF for recurrent GBM<sup>7</sup>.

Vymazal et al.<sup>8</sup> analyzed the response patterns in individuals who exhibited an objective response to TTF in two previous studies in order to evaluate the baseline characteristics of those individuals who responded and to evaluate the relationship between compliance with use and efficacy outcomes. The analysis was completed on one pilot study ( $n=10$ ) and a phase III trial ( $n=237$ ) in which TTF was compared to standard chemotherapy. Between both studies, TTF was administered as monotherapy in 130 individuals. Across both trials, there was a 15% response rate (16/110 with a 4% complete response rate)<sup>8</sup>. There were no significant differences in baseline characteristics between the responder and nonresponder groups. In those in which a response was noted, there was frequently a delayed response; the tumor would initially continue to grow before responding to treatment. Analysis supported that an increase in compliance was associated with better treatment response and longer OS. The extent of treatment response in those who exhibited a response was dependent on compliance ( $p<0.001$ )<sup>8</sup>.

Although Optune is promising for the treatment of newly diagnosed glioblastoma, there is insufficient evidence to promote it as standard of care at this time. Evidence is stronger for recurrent glioblastoma which has been previously treated with radiation, surgery and chemotherapy.

#### *NovoTal*

The NovoTal system (Novocure) is a computer software planning tool that helps direct placement of transducer arrays for TTF therapy. Few studies have evaluated outcomes of TTF planned by physicians with and without the use of NovoTal, and these are limited to a case series, physician use study, and two review articles. Additionally, many of the authors reported ties to Novocure.

**Coding Implications**

Codes referenced in this clinical policy are for informational purposes only. Inclusion or exclusion of any codes does not guarantee coverage. Providers should reference the most up-to-date sources of professional coding guidance prior to the submission of claims for reimbursement of covered services.

HCPSC Codes	Description
A4555	Electrode/transducer for use with electrical stimulation device used for cancer treatment, replacement only
E0766	Electrical stimulation device used for cancer treatment, includes all accessories, any type

**ICD-10-CM Diagnosis Codes that Support Coverage Criteria**

ICD-10-CM Code	Description
C71.0 - C71.9	Malignant neoplasm of brain [supratentorial glioblastomas (WHO grade IV astrocytomas)]

### **Important Reminder**

This clinical policy has been developed by appropriately experienced and licensed health care professionals based on a review and consideration of currently available generally accepted standards of medical practice; peer-reviewed medical literature; government agency/program approval status; evidence-based guidelines and positions of leading national health professional organizations; views of physicians practicing in relevant clinical areas affected by this clinical policy; and other available clinical information. The Health Plan makes no representations and accepts no liability with respect to the content of any external information used or relied upon in developing this clinical policy. This clinical policy is consistent with standards of medical practice current at the time that this clinical policy was approved. "Health Plan" means a health plan that has adopted this clinical policy and that is operated or administered, in whole or in part, by Centene Management Company, LLC, or any of such health plan's affiliates, as applicable.

The purpose of this clinical policy is to provide a guide to medical necessity, which is a component of the guidelines used to assist in making coverage decisions and administering benefits. It does not constitute a contract or guarantee regarding payment or results. Coverage decisions and the administration of benefits are subject to all terms, conditions, exclusions and limitations of the coverage documents (e.g., evidence of coverage, certificate of coverage, policy, contract of insurance, etc.), as well as to state and federal requirements and applicable Health Plan-level administrative policies and procedures.

## CLINICAL POLICY

### Electric Tumor Treating fields

This clinical policy is effective as of the date determined by the Health Plan. The date of posting may not be the effective date of this clinical policy. This clinical policy may be subject to applicable legal and regulatory requirements relating to provider notification. If there is a discrepancy between the effective date of this clinical policy and any applicable legal or regulatory requirement, the requirements of law and regulation shall govern. The Health Plan retains the right to change, amend or withdraw this clinical policy, and additional clinical policies may be developed and adopted as needed, at any time.

This clinical policy does not constitute medical advice, medical treatment or medical care. It is not intended to dictate to providers how to practice medicine. Providers are expected to exercise professional medical judgment in providing the most appropriate care, and are solely responsible for the medical advice and treatment of members. This clinical policy is not intended to recommend treatment for members. Members should consult with their treating physician in connection with diagnosis and treatment decisions.

Providers referred to in this clinical policy are independent contractors who exercise independent judgment and over whom the Health Plan has no control or right of control. Providers are not agents or employees of the Health Plan.

This clinical policy is the property of the Health Plan. Unauthorized copying, use, and distribution of this clinical policy or any information contained herein are strictly prohibited. Providers, members and their representatives are bound to the terms and conditions expressed herein through the terms of their contracts. Where no such contract exists, providers, members and their representatives agree to be bound by such terms and conditions by providing services to members and/or submitting claims for payment for such services.

**Note: For Medicaid members,** when state Medicaid coverage provisions conflict with the coverage provisions in this clinical policy, state Medicaid coverage provisions take precedence. Please refer to the state Medicaid manual for any coverage provisions pertaining to this clinical policy.

**Note: For Medicare members,** to ensure consistency with the Medicare National Coverage Determinations (NCD) and Local Coverage Determinations (LCD), all applicable NCDs, LCDs, and Medicare Coverage Articles should be reviewed prior to applying the criteria set forth in this clinical policy. Refer to the CMS website at <http://www.cms.gov> for additional information.

#### INSTRUCTIONS FOR USE

The following Coverage Policy applies to health benefit plans administered by Cigna Companies. Certain Cigna Companies and/or lines of business only provide utilization review services to clients and do not make coverage determinations. References to standard benefit plan language and coverage determinations do not apply to those clients. Coverage Policies are intended to provide guidance in interpreting certain standard benefit plans administered by Cigna Companies. Please note, the terms of a customer's particular benefit plan document [Group Service Agreement, Evidence of Coverage, Certificate of Coverage, Summary Plan Description (SPD) or similar plan document] may differ significantly from the standard benefit plans upon which these Coverage Policies are based. For example, a customer's benefit plan document may contain a specific exclusion related to a topic addressed in a Coverage Policy. In the event of a conflict, a customer's benefit plan document always supersedes the information in the Coverage Policies. In the absence of a controlling federal or state coverage mandate, benefits are ultimately determined by the terms of the applicable benefit plan document. Coverage determinations in each specific instance require consideration of 1) the terms of the applicable benefit plan document in effect on the date of service; 2) any applicable laws/regulations; 3) any relevant collateral source materials including Coverage Policies and; 4) the specific facts of the particular situation. Coverage Policies relate exclusively to the administration of health benefit plans. Coverage Policies are not recommendations for treatment and should never be used as treatment guidelines. In certain markets, delegated vendor guidelines may be used to support medical necessity and other coverage determinations.

### Coverage Policy

#### [High Resolution Anoscopy \(CPT Codes 46601, 46607\)](#)

**High resolution anoscopy (HRA) is considered medically necessary for diagnosis of EITHER of the following:**

- suspicious anal lesion, including high-grade suspicious intraepithelial lesion (HSIL)
- anal dysplasia found in prior cytology/biopsy

**HRA for any other indication is considered experimental, investigational and unproven.**

#### Whole Body and Selective Head Hypothermia (CPT code 99184)

Whole body or selective head therapeutic hypothermia in a neonate  $\leq 28$  days of age is considered medically necessary for the treatment of moderate or severe hypoxic ischemic encephalopathy.

Whole body or selective head therapeutic hypothermia in a neonate  $\leq 28$  days of age for any other indication is considered experimental, investigational or unproven.

#### Tumor Treatment Fields (TTF) Therapy (HCPCS Codes A4555, E0766, 64999)

TTF therapy (i.e., Optune™) is considered medically necessary for individual 22 years of age or older with presence of histologically-confirmed glioblastoma multiforme (GBM) when EITHER of the following criteria are met:

- with confirmed recurrence after receiving chemotherapy and the device is being used as a monotherapy
- for adjuvant therapy with temozolomide

TTF (i.e., Optune™) for any other indication is considered experimental, investigational or unproven.

The use of treatment planning software (i.e., NovoTAL) (CPT code 64999) for use with tumor treatment fields for any indication, is considered experimental, investigational or unproven.

#### Insertion of Ocular Telescope Prosthesis Including Crystalline Lens (CPT Code 0308T, HCPCS Code C1840)

Intraocular telescope (Implantable Miniature Telescope [IMT]) is considered as medically necessary for an individual 65 years of age or older when ALL of the following criteria are met:

- with stable severe to profound vision impairment (best corrected distance visual acuity 20/160 to 20/800) caused by bilateral central scotomas associated with end-stage age-related macular degeneration (AMD)
- has retinal findings of geographic atrophy or disciform scar with foveal involvement, as determined by fluorescein angiography
- has evidence of visually significant cataract ( $\geq$  grade 2)
- agrees to undergo pre-surgery training and assessment (two to four visits) with low vision specialists (e.g., optometrist or occupational therapist) in the use of an external telescope
- achieve at least a 5-letter improvement on the Early Treatment Diabetic Retinopathy Study (ETDRS) chart with an external telescope on the eye scheduled for surgery
- have adequate peripheral vision in the eye not scheduled for surgery
- agree to participate in postoperative visual training with a low vision specialist

### **EXPERIMENTAL, INVESTIGATIONAL OR UNPROVEN**

#### MarginProbe® (CPT Code 19499)

MarginProbe (CPT code 19499) for any indication is considered experimental, investigational or unproven.

#### Conjunctival Incision with Posterior Extrasccleral Placement of a Pharmacological Agent (CPT Code 68399)

Conjunctival incision with posterior extrasccleral placement of a pharmacological agent (CPT Code 68399) for any indication is considered experimental, investigational or unproven.

**Multivariate Analysis of Patient Specific Findings with Quantifiable Computer Probability Assessment (CPT Code 99199)**

Multivariate analysis of patient specific findings with quantifiable computer probability assessment (CPT code 99199) is considered experimental, investigational or unproven.

**Suprachoroidal Delivery of Pharmacological Agent (CPT Code 67299)**

Suprachoroidal delivery of pharmacological agent (CPT code 67299) is considered experimental, investigational or unproven.

**OTHER EXPERIMENTAL, INVESTIGATIONAL OR UNPROVEN SERVICES**

Each of the following services for any indication is considered experimental, investigational or unproven:

CPT®* Codes	Description	Comment
<a href="#">32994</a>	Ablation therapy for reduction or eradication of 1 or more pulmonary tumor(s) including pleura or chest wall when involved by tumor extension, percutaneous, including imaging guidance when performed, unilateral; cryoablation	
<a href="#">33340</a>	Percutaneous transcatheter closure of the left atrial appendage with endocardial implant, including fluoroscopy, transseptal puncture, catheter placement(s), left atrial angiography, left atrial appendage angiography, when performed, and radiological supervision and interpretation	
<a href="#">34806</a>	Transcatheter placement of wireless physiologic sensor in aneurysmal sac during endovascular repair, including radiological supervision and interpretation, instrument calibration, and collection of pressure data (List separately in addition to code for primary procedure)	
<a href="#">34839</a>	Physician planning of a patient-specific fenestrated visceral aortic endograft requiring a minimum of 90 minutes of physician time	
<a href="#">34841</a>	Endovascular repair of visceral aorta (eg, aneurysm, pseudoaneurysm, dissection, penetrating ulcer, intramural hematoma, or traumatic disruption) by deployment of a fenestrated visceral aortic endograft and all associated radiological supervision and interpretation, including target zone angioplasty, when performed; including one visceral artery endoprosthesis (superior mesenteric, celiac or renal artery)	
<a href="#">34842</a>	Endovascular repair of visceral aorta (eg, aneurysm, pseudoaneurysm, dissection, penetrating ulcer, intramural hematoma, or traumatic disruption) by deployment of a fenestrated visceral aortic endograft and all associated radiological supervision and interpretation, including target zone angioplasty, when performed; including two visceral artery endoprostheses (superior mesenteric, celiac and/or renal artery[s])	
<a href="#">34843</a>	Endovascular repair of visceral aorta (eg, aneurysm, pseudoaneurysm, dissection, penetrating ulcer, intramural hematoma, or traumatic disruption) by deployment of a fenestrated visceral aortic endograft and all associated radiological supervision and interpretation, including target zone angioplasty, when performed; including three visceral artery	

	endoprostheses (superior mesenteric, celiac and/or renal artery[s])	
<a href="#">34844</a>	Endovascular repair of visceral aorta (eg, aneurysm, pseudoaneurysm, dissection, penetrating ulcer, intramural hematoma, or traumatic disruption) by deployment of a fenestrated visceral aortic endograft and all associated radiological supervision and interpretation, including target zone angioplasty, when performed; including four or more visceral artery endoprostheses (superior mesenteric, celiac and/or renal artery[s])	
<a href="#">34845</a>	Endovascular repair of visceral aorta and infrarenal abdominal aorta (eg, aneurysm, pseudoaneurysm, dissection, penetrating ulcer, intramural hematoma, or traumatic disruption) with a fenestrated visceral aortic endograft and concomitant unibody or modular infrarenal aortic endograft and all associated radiological supervision and interpretation, including target zone angioplasty, when performed; including one visceral artery endoprosthesis (superior mesenteric, celiac or renal artery)	
<a href="#">34846</a>	Endovascular repair of visceral aorta and infrarenal abdominal aorta (eg, aneurysm, pseudoaneurysm, dissection, penetrating ulcer, intramural hematoma, or traumatic disruption) with a fenestrated visceral aortic endograft and concomitant unibody or modular infrarenal aortic endograft and all associated radiological supervision and interpretation, including target zone angioplasty, when performed; including two visceral artery endoprostheses (superior mesenteric, celiac and/or renal artery[s])	
<a href="#">34847</a>	Endovascular repair of visceral aorta and infrarenal abdominal aorta (eg, aneurysm, pseudoaneurysm, dissection, penetrating ulcer, intramural hematoma, or traumatic disruption) with a fenestrated visceral aortic endograft and concomitant unibody or modular infrarenal aortic endograft and all associated radiological supervision and interpretation, including target zone angioplasty, when performed; including three visceral artery endoprostheses (superior mesenteric, celiac and/or renal artery[s])	
<a href="#">34848</a>	Endovascular repair of visceral aorta and infrarenal abdominal aorta (eg, aneurysm, pseudoaneurysm, dissection, penetrating ulcer, intramural hematoma, or traumatic disruption) with a fenestrated visceral aortic endograft and concomitant unibody or modular infrarenal aortic endograft and all associated radiological supervision and interpretation, including target zone angioplasty, when performed; including four or more visceral artery endoprostheses (superior mesenteric, celiac and/or renal artery[s])	
<a href="#">46999</a>	Unlisted procedure, anus	Considered Experimental/Investigational/ Unproven when used to report transanal radiofrequency therapy for fecal Incontinence (e.g., SECCA procedure)
<a href="#">58674</a>	Laparoscopy, surgical, ablation of uterine fibroid(s) including intraoperative ultrasound guidance and monitoring, radiofrequency	
<a href="#">64999</a>	Unlisted procedure, nervous system	Considered Experimental/Investigational/

		Unproven when used to report implantation of trial or permanent electrode arrays or pulse generators for peripheral subcutaneous field stimulation
<a href="#">83993</a>	Calprotectin, fecal	
<a href="#">84999</a>	Unlisted chemistry procedure	Considered Experimental/Investigational/Unproven when used to report Holotranscobalamin, quantitative (Holtranscobalamin Testing)
<a href="#">88749</a>	Unlisted in vivo (eg, transcutaneous) laboratory service	Considered Experimental/Investigational/Unproven when used to report skin advanced glycation endproducts measurement by multi-wavelength fluorescent spectroscopy
<a href="#">91112</a>	Gastrointestinal transit and pressure measurement, stomach through colon, wireless capsule, with interpretation and report	
<a href="#">91299</a>	Unlisted diagnostic gastroenterology procedure	Considered Experimental/Investigational/Unproven when used to report 13C-Spirulina Gastric Emptying Breath Test (GEBT)
<a href="#">92978</a>	Endoluminal imaging of coronary vessel or graft using intravascular (IVUS) or optical coherence tomography (OCT) during diagnostic evaluation and/or therapeutic intervention including imaging supervision, interpretation and report; initial vessel (List separately in addition to code for primary procedure)	Considered Experimental/Investigational/Unproven when used to report CPT code 92978 using endoluminal imaging of coronary vessel or graft using optical coherence tomography (OCT) during diagnostic evaluation and/or therapeutic intervention including imaging supervision, interpretation and report; initial vessel
<a href="#">92979</a>	Endoluminal imaging of coronary vessel or graft using intravascular (IVUS) or optical coherence tomography (OCT) during diagnostic evaluation and/or therapeutic intervention including imaging supervision, interpretation and report; each additional vessel (List separately in addition to code for primary procedure)	Considered Experimental/Investigational/Unproven when used to report CPT code 92979 using endoluminal imaging of coronary vessel or graft using optical coherence tomography (OCT) during diagnostic evaluation and/or therapeutic intervention including imaging supervision, interpretation and report; each additional

		vessel
<a href="#">93702</a>	Bioimpedance spectroscopy (BIS), extracellular fluid analysis for lymphedema assessment(s)	
<a href="#">93799</a>	Unlisted cardiovascular service or procedure	Considered Experimental/Investigational/Unproven when used to report acoustic cardiography
<a href="#">93982</a>	Noninvasive physiologic study of implanted wireless pressure sensor in aneurysmal sac following endovascular repair, complete study including recording, analysis of pressure and waveform tracings, interpretation and report (Code deleted 12/31/2017)

### Services without Food and Drug Administration (FDA) Approval

This policy discusses the safety and effectiveness of certain technologies, services, and procedures, including those represented by some Category III CPT® codes. Category III codes are temporary codes that allow for data collection for these services/procedures.

Additionally, there are certain codes, including mainly Category III codes that represent services which have not yet received Food and Drug Administration (FDA) approval:

CPT®* Codes	Description	Comment
88749	Unlisted in vivo (eg, transcutaneous) laboratory service	Considered Experimental/Investigational/ Unproven when used to report skin advanced glycation endproducts measurement by multi-wavelength fluorescent spectroscopy
0190T	Placement of intraocular radiation source applicator (List separately in addition to primary procedure)	
0293T	Insertion of left atrial hemodynamic monitor; complete system, includes implanted communication module and pressure sensor lead in left atrium including transseptal access, radiological supervision and interpretation, and associated injection procedures, when performed (Code deleted 12/31/2017)	
0294T	Insertion of left atrial hemodynamic monitor; pressure sensor lead at time of insertion of pacing cardioverter-defibrillator pulse generator including radiological supervision and interpretation and associated injection procedures, when performed (List separately in addition to primary procedure) (Code deleted 12/31/2017)	
0338T	Transcatheter renal sympathetic denervation, percutaneous approach including arterial puncture, selective catheter placement(s) renal artery(ies), fluoroscopy, contrast injection(s), intraprocedural roadmapping and radiological supervision and interpretation, including pressure gradient measurements, flush aortogram and diagnostic renal angiography when performed; unilateral	
0339T	Transcatheter renal sympathetic denervation, percutaneous approach including arterial puncture, selective catheter placement(s) renal artery(ies), fluoroscopy, contrast injection(s), intraprocedural roadmapping and radiological supervision and interpretation, including pressure gradient measurements, flush aortogram and diagnostic renal angiography when performed; bilateral	
0342T	Therapeutic apheresis with selective HDL delipidation and plasma reinfusion	
0404T	Transcervical uterine fibroid(s) ablation with ultrasound guidance, radiofrequency	
0408T	Insertion or replacement of permanent cardiac contractility modulation system, including contractility evaluation when performed, and programming of sensing and therapeutic parameters; pulse generator with transvenous electrodes	
0409T	Insertion or replacement of permanent cardiac contractility modulation system, including contractility evaluation when performed, and programming of sensing and therapeutic parameters; pulse generator only	
0410T	Insertion or replacement of permanent cardiac contractility modulation system, including contractility evaluation when performed, and programming of sensing and therapeutic parameters; atrial electrode only	
0411T	Insertion or replacement of permanent cardiac contractility modulation system, including contractility evaluation when performed, and programming of sensing and therapeutic parameters; ventricular electrode only	

0412T	Removal of permanent cardiac contractility modulation system; pulse generator only	
0413T	Removal of permanent cardiac contractility modulation system; transvenous electrode (atrial or ventricular)	
0414T	Removal and replacement of permanent cardiac contractility modulation system pulse generator only	
0415T	Repositioning of previously implanted cardiac contractility modulation transvenous electrode, (atrial or ventricular lead)	
0416T	Relocation of skin pocket for implanted cardiac contractility modulation pulse generator	
0417T	Programming device evaluation (in person) with iterative adjustment of the implantable device to test the function of the device and select optimal permanent programmed values with analysis, including review and report, implantable cardiac contractility modulation system	
0418T	Interrogation device evaluation (in person) with analysis, review and report, includes connection, recording and disconnection per patient encounter; implantable cardiac contractility modulation system

## **Cardiovascular**

### **Percutaneous transcatheter closure of the left atrial appendage (Codes 33340)**

Minimally invasive procedures for closure of the left atrial appendage (LAA) have been developed for the purpose of prevention of stroke. In an individual with atrial fibrillation (AF); it is a potential source for blood clots to form that lead to stroke. Percutaneous LAA closure devices are a nonpharmacologic alternative to anticoagulation for stroke prevention in AF. It is theorized that the devices may prevent thrombus formation and stroke by occluding the LAA.

The Watchman™ Left Atrial Appendage Closure Device (Boston Scientific, Maple Grove, MN) is a self-expanding nickel-titanium system. Implantation is performed percutaneously with a catheter delivery system, with venous access and trans-septal puncture to enter the left atrium. After implantation of device, patients receive anticoagulation with warfarin or other agents for approximately one to two months. During this acute period of time, anticoagulation may be necessary due to risk of thrombus formation related to altered blood flow around the implant. Patients are monitored with transesophageal echocardiography to assess blood flow and complete LAA closure (LAAC). After this period, patients will receive antiplatelet agents (e.g., aspirin and/or clopidogrel) indefinitely.

Other available devices that have not received FDA approval for the use of LAA closure include:

- The Amplatzer™ Cardiac Plug (St. Jude Medical, Minneapolis, MN) is approved for LAAC in Europe. The device closes off the LAA in a manner similar to the Watchman. The technique for implanting this device is also similar to that of the Watchman™ system.
- The Lariat® Loop Applicator is a suture delivery device that is designed to close a variety of surgical wounds in addition to LAAC. The technical approach differs from that of the Watchman system. The Lariat suture loop ligates the LAA from the epicardial space, with assistance of catheters and balloons in the left atrium.

### **U.S. Food and Drug Administration (FDA)**

The Watchman LAA Closure Technology received FDA premarket approval March 2015. The approval notes that the device is indicated to reduce the risk of thromboembolism from the left atrial appendage (LAA) in patients with non-valvular atrial fibrillation who:

- are at increased risk for stroke and systemic embolism based on CHADS<sub>2</sub> (cardiac failure, hypertension, age ≥ 75 years, diabetes, stroke) or CHA<sub>2</sub>DS<sub>2</sub>-VASc<sup>1</sup> (congestive heart failure, hypertension, age ≥ 75

years, diabetes, stroke/transient ischemic attack/thromboembolism, vascular disease, aged 65 to 74 years, sex category [female]) scores and are recommended for anticoagulation therapy

- are deemed by their physicians to be suitable for warfarin
- have an appropriate rationale to seek a non-pharmacologic alternative to warfarin, taking into account the safety and effectiveness of the device compared to warfarin

Other devices that have not received FDA approval for the use of LAA closure include but are not limited to:

- The Amplatzer™ Cardiac Plug (St. Jude Medical, Minneapolis, MN) is approved for LAAC in Europe. The device closes off the LAA in a manner similar to the Watchman. The technique for implanting this device is also similar to that of the Watchman system.
- The Lariat® Loop Applicator (Sentreheart, Palo Alto, CA) is a suture delivery device that is designed to close a variety of surgical wounds in addition to LAAC. The Lariat Loop Applicator device did receive 510(k) marketing clearance from FDA in 2006 as suture delivery device, but does not have FDA approval as a LAA closure device. Its intended use is to facilitate suture placement and knot tying in surgical applications where soft tissues are being approximated or ligated with a pretied polyester suture. The technical approach differs from that of the Watchman system. The Lariat suture loop ligates the LAA from the epicardial space, with assistance of catheters and balloons in the left atrium.
- PLAATO (Percutaneous Left Atrial Appendage Transcatheter Occlusion) device (Apriva Medical, Inc., Sunnyvale, CA, USA) is no longer in production.

### Literature Review

Saw et al. (2017) reported on a study to evaluate the safety and efficacy of WATCHMAN of 106 patients who underwent WATCHMAN implantation at four major Canadian centers. The indications for left atrial appendage (LAA) closure were CHADS<sub>2</sub> ≥ 1 or CHA<sub>2</sub> DS<sub>2</sub> -VASc ≥ 2, and a contraindication/intolerance to or failure on anticoagulation. Follow-up imaging was typically performed 1-6 months postprocedure. Procedural success was 97.2% (103 of 106): one device embolization (snared percutaneously); one implant failure due to inadequate LAA depth; and, one cardiac perforation requiring surgical repair before WATCHMAN implantation. The composite major safety event-rate was 1.9% (one death and one device embolization). Antithrombotic therapy postimplant included dual antiplatelet therapy in 76 of 103 (73.8%). The mean follow-up was 210±182 days; there were two transient ischemic attacks, with estimated 66% reduction in thromboembolic events relative to CHADS<sub>2</sub> predicted risk. This is a preliminary study of patients with contraindication/intolerance to anticoagulation. The authors note that the results should be confirmed in larger prospective registries and randomized trials in this patient population.

Huang et al. (2017) reported on a single center, prospective, observational study to evaluate the procedural feasibility, safety and 12-month outcomes of the WATCHMAN LAA Occlusion Device in 106 nonvalvular atrial fibrillation (NVAF) patients with high risk for stroke. There was follow-up at one, three, six and 12 months after discharge. A transesophageal echocardiograph was performed at 45 days after implantation. The procedural success rate was 94.3% (100/106), and the occlusion rate was 100.0% (100/100). There were one tamponade, one ischemic stroke, and eight minor pericardial effusions during hospitalization. In the 12-month follow-up period, two patients developed a thrombus layer on the device that resolved with additional anticoagulation: one with visible device-thrombus experienced transient ischemic stroke, and one had a hemorrhagic stroke with no deaths in the study. The overall survival rate was 100.0%, and non-major adverse event rate of 95.0% (95/100). In this study, the expected annual rate of ischemic stroke risk in these patients according to the CHA<sub>2</sub>DS<sub>2</sub>-VASc score was 4.0%, while the observed ischemic stroke rate was 2.0% per year. The authors note that large multi-center trials and long-term follow-up are needed to evaluate the safety and efficacy of this application.

Betts et al. (2017) reported on a retrospective study assessing the feasibility and long-term efficacy of left atrial appendage occlusion (LAAO) in 371 patients in eight centers in the United Kingdom. The device choice was Watchman in 63% of cases, Amplatzer Cardiac Plug in 34.7%, Lariat in 1.7%, and Coherex WaveCrest in 0.6%. The 343 patients who received an LAAO device were followed up for 24.7 ± 16.07 months. The overall procedure success was 92.5%, with major events in 3.5% of cases. A significant improvement in procedure success (from 89.2% to 95.7%; P = 0.018) and reduction of acute major complications (from 6.5% to 0.5%; P = 0.001) were observed between procedures in the first and the second half of the recruitment time. An annual 90.1% relative

risk reduction (RRR) for ischemic stroke, an 87.2% thromboembolic events RRR, and a 92.9% major bleeding RRR were observed, if compared with the predicted annual risks based on CHADS<sub>2</sub>, CHA<sub>2</sub>DS<sub>2</sub>-Vasc, and HAS-BLED scores, respectively. The study was limited by retrospective nature and lack of randomization.

Chen et al. (2017) reported on a retrospective study was designed to compare the feasibility and safety of left atrial appendage closure (LAAC) in primary and secondary stroke preventions. The study included 122 non-valvular atrial fibrillation (AF) patients with CHA<sub>2</sub>DS<sub>2</sub>-VAsC  $\geq 1$  selected for percutaneous LAAC operations. Outcome observations of primary and secondary stroke preventions with Watchman devices were analyzed and compared with 68 for primary stroke prevention and 47 for secondary prevention (included in the secondary prevention group when they had previous histories of stroke/TIA or infarct foci identified by head CT/MRI scan). Trans-esophageal echocardiography (TEE) was performed at 45 days. Both the CHA<sub>2</sub>DS<sub>2</sub>-VAsC score and the HASBLED score were significantly higher in the secondary prevention group ( $4.09 \pm 1.06$  vs.  $1.93 \pm 1.09$  for CHA<sub>2</sub>DS<sub>2</sub>-VAsC and  $1.83 \pm 1.03$  vs.  $1.26 \pm 0.87$  for HASBLED,  $P < 0.01$ ). In both groups LAAC were achieved with high successful rate (98.53% in the primary prevention group and 100% in the secondary prevention group,  $P > 0.05$ ) and low complication rates. In median follow-up of 12 months, stroke rates were found to be at low level in both groups (1.47% in primary prevention group vs. 2.13% in secondary prevention group,  $P > 0.05$ ). Limitations of the study include the lack of comparator group, and that it is a retrospective study. The authors note that prospective clinical trials with larger sample size and longer follow-up period are needed to study the efficacy and safety of LAAC in secondary stroke preventions.

Sahay et al. (2017) reported on a network meta-analysis to assess the efficacy and safety of LAAC compared with other strategies for stroke prevention in patients with AF. The review included randomized controlled trials comparing warfarin with placebo, antiplatelet therapy (APT) or Non-vitamin K antagonist oral anticoagulants (NOAC) in patients with AF using meta-analysis guidelines. Two major trials of LAAC were also included and a network meta-analysis with indirect comparison was performed to compare the impact of LAAC on mortality, stroke/systemic embolism (SE) and major bleeding in relation to medical treatment. The network meta-analysis included 19 RCTs (87,831 patients) with AF receiving anticoagulants, APT, placebo or LAAC. Indirect comparison with network meta-analysis using warfarin as the common comparator revealed efficacy benefit that favored LAAC as compared with placebo (mortality: HR 0.38, 95% CI 0.22 to 0.67,  $p < 0.001$ ; stroke/SE: HR 0.24, 95% CI 0.11 to 0.52,  $p < 0.001$ ) and APT (mortality: HR 0.58, 95% CI 0.37 to 0.91,  $p = 0.0018$ ; stroke/SE: HR 0.44, 95% CI 0.23 to 0.86,  $p = 0.017$ ) and similar to NOAC (mortality: HR 0.76, 95% CI 0.50 to 1.16,  $p = 0.211$ ; stroke/SE: HR 1.01, 95% CI 0.53 to 1.92,  $p = 0.969$ ). LAAC showed comparable rates of major bleeding when compared with placebo (HR 2.33, 95% CI 0.67 to 8.09,  $p = 0.183$ ), APT (HR 0.75, 95% CI 0.30 to 1.88,  $p = 0.542$ ) and NOAC (HR 0.80, 95% CI 0.33 to 1.94,  $p = 0.615$ ). The authors note that the findings of this meta-analysis suggest that LAAC is superior to placebo and APT, and comparable to NOAC for preventing mortality and stroke or SE, with similar bleeding risk in patients with nonvalvular AF. In addition, they note that these results should be interpreted with caution and more studies are needed to further substantiate this advantage, in view of the wide CIs with some variables in the current meta-analysis.

Saw et al. (2017) reported on a study to evaluate the safety and efficacy of WATCHMAN device for left atrial appendage (LAA) closure in 106 patients with nonvalvular atrial fibrillation (AF) and contraindications to anticoagulation. Indications for LAA closure were CHADS<sub>2</sub>  $\geq 1$  or CHA<sub>2</sub> DS<sub>2</sub> -VAsC  $\geq 2$ , and a contraindication/intolerance to or failure on anticoagulation. Follow-up imaging was performed one to six months post-procedure. The mean age of patients was  $74.8 \pm 7.7$ , mean CHADS<sub>2</sub> score was  $2.8 \pm 1.2$ , CHA<sub>2</sub> DS<sub>2</sub> -VAsC score was  $4.3 \pm 1.5$ , and HASBLED score was  $3.2 \pm 1.2$ . Indications for LAA closure were prior bleeding 89.6% (87 major bleeding and 8 minor bleeding), 9.4% were deemed high risk for bleeding, and 0.9% with recurrent strokes on warfarin. Procedural success was 97.2% (103 of 106), with one device embolization, one implant failure due to inadequate LAA depth, and one cardiac perforation requiring surgical repair before WATCHMAN implantation. The composite major safety event-rate was 1.9% (1 death and 1 device embolization). Antithrombotic therapy post-implant included dual antiplatelet therapy in 76 of 103 (73.8%). Mean follow-up was  $210 \pm 182$  days; there were two transient ischemic attacks, with estimated 66% reduction in thromboembolic events relative to CHADS<sub>2</sub> predicted risk. The authors note that LAA closure with the WATCHMAN device for patients with nonvalvular AF and contraindications to OAC is safe and effective, and the results should be confirmed in larger prospective registries and randomized trials in this population.

Noelck et al. (2016) reported on a systematic review benefits and harms of surgical or percutaneous LAA exclusion procedures. The review included controlled clinical trials that assessed the effectiveness of percutaneous LAA exclusion procedures and to assess the harms of percutaneous LAA procedures cohort and registry studies with 50 or more patients were included. For percutaneous interventions, the review included two randomized controlled studies and 11 registry studies. The findings note that there is low-strength evidence that percutaneous LAA exclusion is associated with a similar risk of long-term stroke and mortality as continued oral anticoagulation therapy. The finding is based on trials of one device (Watchman) studied in patients without contraindications to oral anticoagulant therapy. Most patients who received the Watchman device were able to discontinue oral anticoagulant therapy after undergoing follow-up transesophageal echocardiography (TEE) showing persistent closure of the LAA at three to six months. The review found that there is moderate strength evidence that a substantial proportion of patients undergoing various percutaneous LAA exclusion procedures experienced serious periprocedural harms with insufficient evidence to determine whether factors such as operator experience, patient selection criteria, or choice of device can modify these risks. In addition, it was noted that there is insufficient data to assess the balance of benefits and harms of percutaneous LAA exclusion procedures in patients who are ineligible for long-term oral anticoagulation therapy.

Boersma et al. (2016) reported on peri-procedural outcomes of up to 30-days from the prospective, multicenter registry (EWOLUTION). Baseline/implant data were available for 1021 subjects with high risk of stroke and moderate-to-high risk of bleeding. The device was successfully deployed in 98.5% of patients with no flow or minimal residual flow achieved in 99.3% of the implanted patients. Thirty-one serious adverse events (SAEs) were noted in 28 subjects within 1 day of the procedure. The overall 30-day mortality rate was 0.7%. The most common SAE that occurred within 30 days of the procedure was major bleeding requiring transfusion. The incidence of SAEs within 30 days was lower for subjects deemed to be ineligible for oral anticoagulation therapy (OAT) compared with those eligible for OAT (6.5 vs. 10.2%,  $P = 0.042$ ). The study is limited by lack of randomization, and short term follow-up. Boersma et al. (2017) reported on one-year follow-up of the EWOLUTION trial. At one year, mortality was 9.8%, noted by the author that is reflected the advanced age and comorbidities in the population. Device thrombus was observed in 28 patients at routine TEE (3.7%) and was not correlated with the drug regimen ( $P = .14$ ). Ischemic stroke rate was 1.1% (relative risk 84% vs estimated historical data); the major bleeding rate was 2.6% and was predominantly (2.3%) nonprocedure/device related.

A noninferiority randomized, controlled trial (RCT) compared LAA closure with Watchman device to warfarin treatment in patients with non-valvular atrial fibrillation (NVAF), the PROTECT AF trial (Holmes, et al., 2009; Reddy, et al., 2013a; Reddy, et al. 2014). The trial included 707 patients, randomized 2:1, with the device group  $n=463$  and warfarin group  $n=244$  and a follow-up time was  $3.8 \pm 1.7$  years (Reddy et al., 2014). Inclusion criteria: age  $\geq 18$  years; paroxysmal, persistent, or permanent NVAF and eligible for warfarin treatment; and, CHADS<sub>2</sub> score  $\geq 1$ . In the Watchman group the device implanted under transesophageal echocardiography (TEE) guidance with concomitant warfarin and Aspirin (ASA) (81-325 mg/day) for 45 days, on day 45, warfarin stopped, clopidogrel (75 mg/day) started until six month visit and then only ASA continued. In the warfarin group warfarin treatment was provided with a target INR 2-3. The primary efficacy outcome was stroke, systemic embolization, or cardiovascular death. The primary safety outcome was a composite of major bleeding events and procedure-related complications. At mean follow-up of 3.8 years, there were 39 events in 463 pts (8.4%) in the device group for primary event per 100 patient/years (pt/yr), compared with 34 events in 244 patients (13.9%) for primary event rate of 3.8 in 100 pt/yr in warfarin group. In the primary efficacy outcome, there was a noninferiority  $>99\%$ , and in the primary safety endpoint a noninferiority  $>98\%$ . Complications included in the Watchman group: serious pericardial effusion (4.8%); major bleeding (4.8%); procedure related ischemic stroke (1.3%); device embolization (0.6%); and hemorrhagic stroke (0.6%). In the warfarin group: major bleeding (7.4%); and, hemorrhagic stroke (3.7%). This study demonstrated the noninferiority of LAA closure compared to warfarin treatment. The study was limited in that it included warfarin, but did not include a comparison with the newer anticoagulants. The study included patients with warfarin, but does not address the patients who are unable to take anticoagulants.

A noninferiority RCT of that compared LAA closure with Watchman device and long-term warfarin treatment in pts with NVAF, the PREVAIL study (Holmes, et al., 2014). The study included 407 patients (randomized 2:1); with 68 patients enrolled through roll-in process with the Watchman group,  $n=269$  and warfarin group,  $n=138$ . The follow-up time was a median of 12 months. The inclusion criteria included: NVAF; CHADS<sub>2</sub>  $\geq 2$  or 1 CHADS<sub>2</sub> plus 1 high-risk characteristic. In the Watchman group, the device was implanted guided by fluoroscopy and

TEE; post-implant patients were treated with warfarin and ASA for 45 days; TEE performed at 45 days, 6 months, and 12 months. Warfarin was discontinued if the day 45 TEE documented closure of LAA or residual peri-device flow <5 mm and no definite visible large thrombus on device; then clopidogrel 75 mg/day and ASA 81-325 mg/day was prescribed until six months when clopidogrel discontinued. In the warfarin group warfarin treatment was given with target INR 2.0-3.0. At 18 months, the rate of the first coprimary efficacy endpoint (composite of stroke, systemic embolism [SE], and cardiovascular/unexplained death) was 0.064 in the device group versus 0.063 in the control group and did not achieve the prespecified criteria noninferiority. The rate for the second coprimary efficacy endpoint (stroke or SE >7 days' post-randomization) was 0.0253 versus 0.0200 achieving noninferiority. Early safety events occurred in 2.2% of the Watchman arm. Complications (reported for Watchman-group only) (% of patients): device embolization (0.7%); arteriovenous fistula (0.4%); cardiac perforation (0.4%); pericardial effusion with cardiac tamponade (0.4%); major bleed requiring transfusion (0.4%). Noninferiority was not achieved for overall efficacy in this study. The patients in this study were required to be candidates for long-term anticoagulation to facilitate randomization against a control group treated with warfarin. The trial does not address the safety and efficacy of LAA occlusion when anticoagulation is contraindicated. In addition, the study does not include comparison with new oral anticoagulants.

Hayes published a technology assessment for the use of percutaneous LAA closure devices to reduce risk of stroke in patient with atrial fibrillation (AF) (Hayes 2015; 2016; 2017). It was noted that among the four studies that evaluated the efficacy of Watchman in stroke prevention in patients with non-valvular AF (NVAf), the 2 RCTs found this device to be noninferior compared with warfarin OAC in almost all primary measures. Both uncontrolled studies that compared observed versus expected stroke rates reported a lower observed rate in patients implanted with the Watchman device; however, neither study included a statistical test of significance. Regarding safety, LAA closure with the Watchman device is associated with a low but measurable risk of significant procedural/device-related complications such as major bleeding, pericardial effusion, stroke, device embolization, and cardiac perforation or tamponade. The conclusion included these findings regarding the Watchman device:

- Available evidence supports the use of the Watchman device for its FDA-approved indication in LAA closure.
- Since following implantation of the Watchman device patients must continue on warfarin therapy for approximately 45 days, there are very limited data on if and how to use the Watchman device in patients with absolute contraindications to warfarin.
- There would be a benefit from randomized studies that compare device-mediated LAA closure against treatment with the newer OACs and that test the use of the newer OACs as an adjunct to LAA closure.
- Trials are needed to help identify the patient subgroups that would most benefit from LAA closure.

#### **Professional Societies/Organizations**

##### **American College of Cardiology (ACC)/American Heart Association (AHA)/Heart Rhythm Society (HRS):**

These organizations published joint guidelines for the management of patients with atrial fibrillation (January, et al., 2014). The guidelines include a discussion of percutaneous occlusion of the LAA but do not provide specific recommendations regarding the use of these devices.

**American Heart Association (AHA)/American Stroke Association (ASA):** Joint guidelines from these organizations for the primary prevention of stroke include the following recommendations regarding LAA closure (Meschia, et al., 2014):

- closure of the LAA may be considered for high-risk patients with AF who are deemed unsuitable for anticoagulation
- performed at a center with low rates of periprocedural complications
- the patient can tolerate the risk of at least 45 days of post-procedural anticoagulation

(Class IIb; Level of Evidence B)

Level of evidence B: limited populations evaluated. Data derived from a single randomized trial or nonrandomized studies.

Class IIb: recommendation's usefulness/efficacy less well established; greater conflicting evidence from single randomized trial or nonrandomized studies

#### **Use Outside of the US**

**Canadian Cardiovascular Society (CCS):** The CCS published guidelines for the management of atrial fibrillation (Verma, et al., 2014). The guidelines note the following regarding LAA closure devices:

- LAA closure devices are not currently approved for use in Canada.
- It is suggested that these non-approved LAA closure devices not be used, except in research protocols or in systematically documented use protocols in patients at high risk of stroke (CHADS<sub>2</sub> score  $\geq 2$ ) for whom antithrombotic therapy is precluded (Conditional Recommendation, Low-Quality Evidence).

**European Society of Cardiology (ESC):** The ESC published updated guidelines for management of atrial fibrillation (Kirchhof, et al., 2016). The guidelines noted:

Recommendations for occlusion or exclusion of the left atrial appendage:

- After surgical occlusion or exclusion of the LAA, it is recommended to continue anticoagulation in at-risk patients with AF for stroke prevention.

Class I\*

Level B

- LAA occlusion may be considered for stroke prevention in patients with AF and contra-indications for long-term anticoagulant treatment (e.g. those with a previous life-threatening bleed without a reversible cause).

Class IIb\*

Level B

- Surgical occlusion or exclusion of the LAA may be considered for stroke prevention in patients with AF undergoing cardiac surgery.

Class IIb\*

Level B

- Surgical occlusion or exclusion of the LAA may be considered for stroke prevention in patients undergoing thoracoscopic AF surgery.

Class IIb\*

Level B

\*Class of recommendations:

Class I - Evidence and/or general agreement that a given treatment or procedure is beneficial, useful, effective.

Class IIb - established by evidence/opinion. Usefulness/efficacy is less well established by evidence/opinion.

Level of evidence:

B Data derived from a single randomized clinical trial or large non-randomized studies.

**European Heart Rhythm Association (EHRA)/European Association of Percutaneous Cardiovascular Interventions (EAPCI):** EHRA/EAPCI published expert consensus statement on catheter-based left atrial appendage occlusion (Meier, et al., 2014). The statement includes the following:

- The main indication for LAA occlusion is AF with a CHADS<sub>2</sub> score  $\geq 1$  or CHA<sub>2</sub>-DS<sub>2</sub>-VASc score  $\geq 2$  and a relative or absolute contraindication to prolonged oral anticoagulation.
- Tolerance for at minimum several weeks of dual antiplatelet therapy, usually followed by lifelong single antiplatelet drug therapy.

**National Institute for Health and Care Excellence (NICE):** NICE clinical guidelines for the management of atrial fibrillation include the following recommendations regarding LAA closure (2010):

- Consider left atrial appendage occlusion (LAAO) if anticoagulation is contraindicated or not tolerated and discuss the benefits and risks of LAAO with the person.
- Do not offer LAAO as an alternative to anticoagulation unless anticoagulation is contraindicated or not tolerated.

**Chronic baroreceptor stimulation of the carotid sinus (CPT codes 0266T, 0267T, 0268T, 0269T, 0270T, 0271T, 0272T, 0273T)**

The Barostim<sup>®</sup> neo implantable device (CVRx, Minneapolis, MN) is proposed to address cases of unmet treatment needs in patients with drug resistant hypertension. The Barostim neo device has replaced the Rheos Baroreflex Hypertension device. The device consists of an implantable pulse generator (IPG), one connecting lead wire, and an external wireless programmer system that allows physicians to modify device therapy. It is implanted under the skin beneath the collar bone with the lead positioned outside the carotid artery to conduct energy from the IPG to carotid baroreceptors. Activated baroreceptors signal the brain to respond to a rise in blood pressure. The brain responds by stimulating pathways of the autonomic nervous system responsible for arterial vessel dilation, heart rate, and fluid excretion. The device is also being investigated for use in heart failure.

**U.S. Food and Drug Administration (FDA)**

December 2014 the Barostim neo<sup>®</sup> Legacy System received humanitarian device exemption (HDE). The device is indicated for use in patients with resistant hypertension who have had bilateral implantation of the Rheos<sup>®</sup> Carotid Sinus Leads Models 1010R, 1010L, 1014L, and 1014R (which have been discontinued and are obsolete) and were determined responders in the Rheos<sup>®</sup> pivotal clinical study.

**Literature Review**

Wallbach et al. (2016) reported on a prospective study that evaluated ambulatory BP measurement (ABPM) data in patients with therapy-refractory hypertension (HTN) treated with the Baroreflex activation therapy (BAT) neo device. ABPM was performed before BAT implantation and six months after initiation of BAT. A total of 51 patients were included into this study, with seven dropping out from analysis. After six months, 24-hour ambulatory systolic (from 148 ± 17 mm Hg to 140 ± 23 mm Hg, P<0.01), diastolic (from 82 ± 13 mm Hg to 77 ± 15 mm Hg, P<0.01), day- and night-time systolic and diastolic BP (all P ≤ 0.01) decreased while the number of prescribed antihypertensive classes could be reduced from 6.5 ± 1.5 to 6.0 ± 1.8 (P=0.03). Heart rate and pulse pressure remained unchanged. BAT was equally effective in reducing ambulatory BP in all subgroups of patients. The authors note that randomized controlled trials are needed to evaluate BAT effects on ABPM in patients with resistant hypertension accurately. This study is limited by the small number of subjects and lack of randomization.

Biognano et al. (2011) published the pivotal study regarding Baroreflex activation therapy (BAT) of the Rheos device. Patients were randomized to receive either active BAT (group A, n=181) or deferred BAT (group B, n=84) with the Rheos system. Active BAT was initiated one month after implantation, while deferred BAT was started seven months after implantation. This design allowed short term comparison between BAT and medical management. The coprimary endpoints: 1) acute systolic blood pressure (SBP) responder rate at 6 months; 2) sustained responder rate at 12 months; 3) procedure safety; 4) BAT safety; and 5) device safety. At 6-month follow-up, 54% of active group patients and 45% of those not receiving active therapy achieved the preset acute efficacy goal of at least 10 mm Hg reduction in (SBP); between-group comparison was not statistically significant. The 30-day rate of procedure- or device-related serious adverse events was 25.5%, which did not meet the preset objective performance criterion (OPC) for procedural safety. Although the 12-month sustained efficacy endpoint was met, this endpoint was assessed by comparing Group A patient outcomes with OPC rather than with Group B outcomes, leading to difficulty in interpretation of the clinical relevance of this result. The long-term device safety and short-term BAT safety primary outcomes were met.

Following completion of the randomized Rheos Pivotal Trial, Bakris et al. (2012) conducted an open-label, nonrandomized single-arm follow-up to assess safety and efficacy of BAT. Blood pressure reductions were measured relative to a pre-implant baseline as well as the results achieved at the completion of 1 year of follow-up in the randomized phase. Clinically significant responder status was assessed according to FDA-mandated criteria. Of the 322 patients implanted, 76% (n=245) qualified as clinically significant responders, an additional 10% were indeterminate. Among long-term responders receiving BAT, the mean blood pressure drop was 35/16 mm Hg. Among responders, 55% achieved goal blood pressures (<140 mm Hg or <130 mm Hg in diabetes or kidney disease). Blood pressures of all active patients remained stable from completion of the randomized phase through long-term follow-up. BAT substantially reduced arterial pressure for most patients participating in the Rheos Pivotal Trial. This blood pressure reduction or goal achievement was maintained over long-term follow-up of 22 to 53 months.

**Endovascular Repair of Visceral Aorta for Abdominal Aortic Aneurysm (including planning) (CPT Codes 34806, 34839, 34841, 34842, 34843, 34844, 34845, 34846, 34847, 34848, 93982) (Codes 34806, 93982 deleted 12/31/2017)**

The conventional treatment for AAA has been open surgical repair. Open surgical repair involves transabdominal surgery, exposure of the aneurysm, cross-clamping the aorta, resection of the aneurysm, and placement of graft prosthesis. Endovascular AAA repair developed as a minimally invasive alternative to open surgical repair in patients with suitable anatomy. Endovascular repair of infrarenal abdominal or aortoiliac AAA has demonstrated reduced rates of perioperative mortality and morbidity compared to open surgical repair, with equivalent long-term aneurysm-related mortality, although this approach is associated with higher rates of reintervention, and requires long-term radiological monitoring. Endovascular repair may be a reasonable option for selected patients with suitable anatomy for whom the risk/benefit ratio favors endovascular repair.

The use of fenestrated grafts (e.g., Zenith® Fenestrated AAA Endovascular Graft) has been investigated for the treatment of patients with AAA involving the visceral arteries. These grafts include fenestrations, or scallops, in the graft material that allow the proximal edge of the material to be placed above the renal arteries while permitting blood flow to vessels accommodated by the fenestrations. Evidence published in the medical literature consists primarily of registry data, small feasibility studies, and case series with limited outcome data. Additional evidence is needed to determine the safety, efficacy, and long-term outcomes of this procedure and to determine how this approach compares to surgical repair.

**U.S. Food and Drug Administration (FDA)**

A number of devices have received approval through the FDA Premarket Approval (PMA) process for endovascular treatment of AAA, including the following:

- AneuRx® Stent Graft System (Medtronic Vascular, Santa Rosa, CA)
- Zenith® AAA Endovascular Graft and H&L-B One-Shot™ Introduction System (Cook Incorporated, Bloomington, IN)
- EXCLUDER™ Bifurcated Endoprosthesis (W.L. Gore & Associates, Inc., Flagstaff, AZ)
- Endologix PowerLink® System (Endologix, Inc., Irvine, CA).
- Talent™ Abdominal Stent Graft System (Medtronic Vascular, Santa Rosa, CA)
- Endurant Stent Graft System (Medtronic Vascular, Santa Rosa, CA)

The Zenith® Fenestrated AAA Endovascular Graft (with the adjunctive Zenith Alignment Stent) received FDA PMA approval on December 22, 2011. The Zenith graft is indicated for the endovascular treatment of patients with abdominal aortic or aortoiliac aneurysm having morphology suitable for endovascular repair, including:

- Adequate iliac/femoral access compatible with required introduction systems
- Nonaneurysmal infrarenal aortic segment (neck) proximal to the aneurysms with:
  - Length ≥ 4 mm and unsuitable for a non-fenestrated graft
  - Diameter ≤ 31 mm and ≥ 19 mm
  - Angle < 45 degrees relative to long axis of aneurysm
  - Angle < 45 degrees relative to axis of suprarenal aorta
- Ipsilateral iliac artery fixation site > 30 mm in length and between 9- 21 mm in diameter
- Contralateral iliac artery distal fixation site >30 mm in length and between 7 – 21 mm in diameter

The Zenith Alignment Stent is indicated for use as an adjunct to the Zenith Fenestrated AAA Endovascular Graft to secure positive alignment of fenestrations or scallops with the orifice of aortic branch vessels having diameters ranging from 3 to 8 mm. Unlike the standard Zenith AAA Endovascular Graft, the Zenith Fenestrated AAA graft has fenestrations or scallops in the graft material, which allow the proximal edge of graft material to be placed above the renal arteries while still permitting blood flow to vessels accommodated by the fenestrations or scallops. In order to account for anatomical variation, each proximal body graft is made to order for a specific patient. The Zenith fenestrated graft has been available outside the U.S. since 2002.

The CardioMEMS EndoSure™ Wireless AAA Pressure Measurement System was approved for marketing through the 510(k) process on October 12, 2006 for the measurement of intrasac pressure during endovascular

AAA repair and for use as an adjunctive tool in the detection of intraoperative leaks. In a subsequent approval on March 15, 2007, measurement of intrasac pressure during thoracic aortic aneurysm repair was added as an intended use.

According to the 510(k) summary, the sensor is implanted in the aneurysm sac during stent graft deployment and is left in place in the excluded portion of the aneurysm as a permanent implant. The main body of the sensor is composed of fused silica coated in silicone. Nitinol loops extend from and surround the sensor body. The sensor is interrogated using the antenna of the EndoSure Electronics System. Once the signal is acquired, a pressure waveform and numerical pressure data are displayed on the touch-screen, and a printout of the data and waveform is generated.

### Literature Review

Hayes published a technology directory report on endovascular repair of abdominal aortic aneurysms (AAA) (Hayes 2013; 2016; 2017). The review included 11 randomized controlled trials (RCTs). The RCTs of endovascular aneurysm repair (EVAR) indicate that outcomes are comparable with open surgery for large aneurysms in need of repair, with surveillance for small aneurysms, and with open surgery for the treatment of ruptured aneurysms. The six trials that compared EVAR with open surgery for unruptured AAAs generally found lower 30-day mortality rates with EVAR than with open surgery, but intermediate-term (one to four years) survival and long-term survival (5+ years) were not different between groups, which suggests that the benefit of EVAR occurs in the immediate postoperative period. Of the five studies that reported health-related quality of life (HRQL) results, three found an early benefit with EVAR that was not maintained past three to six months. Complication rates were not consistently different between groups, with the exception that reintervention rates were higher with EVAR than with open surgery in several trials. In the two RCTs that compared EVAR with surveillance for small unruptured AAAs, no differences were observed between groups in 30-day mortality or intermediate-term survival. One study found significantly higher HRQL scores in the EVAR group than in the surveillance group at six months, but the differences were nonsignificant as the study progressed with both studies stopped early based on futility analyses. In the single study that compared EVAR with no treatment for large unruptured AAAs in patients unfit for open surgery, 7% of patients died within 30 days due to EVAR procedure-related causes. No differences between groups were noted in survival or HRQL after up to four years of follow-up (median, 2.4 years), but complications were significantly higher in the EVAR group than in the surveillance group. Two small RCTs (32 and 116 patients) compared EVAR with open repair of ruptured AAA, but neither study found differences in 30-day mortality rates between groups or in overall rates of moderate or severe complications. Mortality rates also did not differ in the study that followed patients for up to two years. The review noted limitations of the RCTs that included the lack of blinding procedures for patients and assessors for many outcome measures. In addition, the studies included a preponderance of males; although no systematic differences in outcomes between men and women were apparent. The surgeries in these studies were performed by experienced surgical teams, and it is uncertain whether these results would generalize to groups with less experienced surgeons. Additionally, in the studies that included surveillance groups for small AAAs, screening procedures were required every six months to monitor AAA size and growth rate; it is therefore uncertain whether the results with the surveillance group would apply to patients with AAAs that are screened less frequently.

**Endovascular Repair Using a Fenestrated Graft:** The British Society for the Endovascular Therapy and the Global Collaborators on Advanced Stent-Graft Repair (GLOBALSTAR) Registry published early results of endovascular repair of juxtarenal aortic aneurysms using the Zenith fenestrated graft in the United Kingdom (2012). Data from 318 patients treated at 14 experienced centers (i.e., > 10 procedures) were retrospectively studied. The primary procedural success rate was 99% (316/318); perioperative mortality was 4.1%; and intraoperative target vessel loss was observed in 5 of 889 target vessels (0.6%). The early reintervention rate (i.e., <30 days) was 7%. There were 11 deaths during the follow-up, but none were aneurysm-related. Freedom from target-vessel loss at one, two, and three years was 93%, 91%, and 85%, respectively, and freedom from late secondary intervention (> 30 days) was 90%, 86%, and 70% at one, two and three years, respectively. The authors stated that these results support continued use and evaluation of this technique for juxtarenal aneurysms, but illustrate the need for a more robust evidence base.

Amiot et al. (2010) conducted a retrospective analysis to evaluate the medium-term outcomes of aortic aneurysm repair using the Zenith fenestrated graft in 16 French academic centers (n=134). Patients were considered to be

at high risk for open surgical repair. The median aneurysm size was 56 mm (range 45-91 mm), and the median patient age was 73 years (range 43-91 years). A total of 403 visceral vessels were treated, including 265 renal arteries. One early conversion to surgery was required. Angiography immediately following the procedure demonstrated patency in 398 of 403 target vessels. The 30-day mortality was 2%. Imaging prior to discharge revealed 16 (12%) endoleaks (3 type I, 12 type II, and 1 type III). Transient or permanent dialysis was required in 4 (3%) and two (1%) patients, respectively. During a median follow-up of 15 months (range 2-53 months), no aneurysms ruptured or required open conversion. Aneurysm sac size decreased by more than 5 mm in 52%, 65.6%, and 75% of patients at one, two and three years, respectively. Three patients had sac enlargement within the first year associated with persistent endoleaks. Four renal artery occlusions were detected during follow-up, and 12 procedures related to reintervention were performed in 12 patients, including six to correct endoleaks and five to correct threatened visceral vessels. Twelve of 131 patients died during follow-up; none of these were aneurysm related.

Greenberg et al. (2009) reported intermediate results of a multicenter prospective case series to assess the safety and efficacy of the Zenith fenestrated devices (n=30) in patients with juxtarenal AAA. Inclusion criteria consisted of aortic or aortoiliac aneurysms with diameter greater than five cm, or with aortic or aortoiliac aneurysms with a history of growth greater than 0.5 cm per year or clinical indication for AAA repair. Customized devices were designed for each patient based on calculations derived from computed tomography (CT) scan data. A total of 77 visceral vessels were accommodated by fenestrations within the sealing segment of the grafts. The most common design accommodated two renal arteries and the superior mesenteric artery (66.7%). Prostheses were successfully implanted in all patients. Of the 30 patients, 27 were available for follow up at 12 months, and 23 were available at 24 months. There were no aneurysm related deaths, aneurysm ruptures, or conversions during the follow-up period. There were no type I or type III endoleaks reported. Type II endoleaks were reported in six patients (26.1%) at 12 months, and in four (20.0%) at 24 months. None of the patients had aneurysm growth > 5 mm. Aneurysm size at 24 months decreased in 16 of 23 patients (69.6%) and was stable in the remaining patients. A renal event occurred in eight patients. Secondary interventions were performed in five patients. No patients experienced renal failure requiring dialysis. The authors concluded that the intermediate term results of this multicenter study are concordant with previous single-center studies and support the concept the placement of fenestrated endovascular grafts is safe and effective at centers with experience in endovascular repair and renal/mesenteric stent placement.

An Agency for Healthcare Research and Quality (AHRQ) evidence report/technology assessment (Wilt et al., 2006) compared endovascular and open surgical repairs for AAA. Randomized controlled trials of open surgical repair, endovascular repair, or active surveillance; systematic reviews; nonrandomized U.S. trials; and national registries were used to assess clinical outcomes. The assessment concluded that for AAA < 5.5 cm in diameter, active surveillance with delayed open surgical repair results in equivalent mortality, but less morbidity, due to fewer interventions, compared to immediate open surgical repair. Endovascular repair of aneurysms ≥ 5.5 cm has not been shown to improve long-term survival or health status compared to open surgical repair, although perioperative outcomes are improved. The assessment also stated that endovascular repair does not improve survival in patients who are medically unfit for open surgical repair. Endovascular repair is associated with more complications, need for reintervention, and monitoring compared to open surgical repair or no intervention. The AHRQ report recommended U.S. randomized controlled trials be conducted with approved endovascular repair devices to evaluate patient outcomes.

**CardioMEMS EndoSure Wireless AAA Pressure Measurement System:** Published evidence on the use of the CardioMEMS system consists of several diagnostic cohort studies with short-term preliminary results (Hoppe et al., 2008, n=12; Silveira et al., 2008, n=25; Ohki et al., 2007, n=76). The safety and clinical utility of this technology in the intraoperative or long-term monitoring of patients following endovascular aortic aneurysm repair has not been established.

**Endovascular repair of iliac artery bifurcation (CPT 0254T, 0255T) (Code 0255T deleted 12/31/2017, use 0254T to report):**

Involvement of the common iliac arteries occurs in approximately 20% of patients with abdominal aortic aneurysms (AAA) and may present a challenge to endovascular treatment since it may compromise sealing and distal fixation of endoprostheses. Several techniques have been developed to achieve the goal of sealing the aneurysmal sac, with one of the techniques is developed of an endoprosthesis for use in the iliac arteries. A device that has been developed exclusively for use in the iliac arteries is the GORE® EXCLUDER® Iliac Branch Endoprosthesis (IBE) (W. L. Gore & Associates, Inc., Flagstaff, AZ). It is intended to be used in conjunction with the Gore Excluder abdominal aortic aneurysm (AAA) endoprosthesis to isolate the common iliac artery from the systemic blood flow and is intended to preserve blood flow to the external and internal iliac arteries and preserve pelvic perfusion (Hayes, 2017).

**U.S. Food and Drug Administration (FDA)**

The GORE® EXCLUDER® Iliac Branch Endoprosthesis (IBE Device) received FDA premarket (PMA) approval February 2016. It is indicated for use with the GORE® EXCLUDER® AAA Endoprosthesis to isolate the common iliac artery from systemic blood flow and preserve blood flow in the external iliac and internal iliac arteries in patients with a common iliac or aortoiliac aneurysm, who have appropriate anatomy that includes:

- Adequate iliac/femoral access
- Minimum common iliac diameter of 17 mm at the proximal implantation zone of the IBE
- External iliac artery treatment diameter range of 6.5-25 mm and seal zone length of at least 10 mm
- Internal iliac artery treatment diameter range of 6.5-13.5 mm and seal zone length of at least 10 mm
- Adequate length from the lowest major renal artery to the internal iliac artery to accommodate the total endoprosthesis length, calculated by adding the minimum lengths of required components, taking into account appropriate overlaps between components

Contraindications to the device include:

- Patients with known sensitivities or allergies to the device materials. All components of the GORE EXCLUDER Iliac Branch Endoprosthesis and the GORE EXCLUDER AAA Endoprosthesis contain ePTFE, FEP, nitinol (nickel-titanium alloy), and gold.
- Patients with a systemic infection who may be at increased risk of endovascular graft infection.

### Literature review

van Sterkenburg et al. (2016) reported on a retrospective cohort analysis that analyzed procedural success and early outcome of endovascular treatment of a multicenter cohort of patients (n=46) with common iliac artery (CIA) aneurysms treated with the GORE EXCLUDER. The median diameter of the treated aneurysm was 40.5 (range, 25.0-90.0) mm and the mean procedural time was 198 ± 56 minutes. One implantation was not successful; two type 1b endoleaks were noticed, which resulted in procedural success rate of 93.5%. The two type 1b endoleaks spontaneously disappeared at 30 days and there was no 30-day mortality. Ipsilateral buttock claudication was present in two cases at 30 days and disappeared during follow-up. The incidence of reported erectile dysfunction was low and there was an absence of severe ischemic complications. After a mean follow-up of six months, data on 17 treated aneurysms were available: these showed two with a stable diameter, and 15 showed a mean decrease of 3.9 ± 2.2 mm (P<.001). Re-interventions were done in two patients (7.1%). The six-month primary patency of the internal component of the IBE device was 94%. The authors noted that prospective data with longer follow-up are awaited to establish the role of the device in the treatment algorithm of CIA aneurysms. Limitations of the study include small sample size and retrospective nature of the study.

### Use Outside of the US

CE Marking for this product was issued in 2013.

**European Society for Vascular Surgery:** this organization published clinical guidelines for the management of abdominal aortic aneurysms (Moll, et al., 2011). Recommendations regarding the management of iliac aneurysms include:

- Coexisting iliac aneurysms should be treated concurrently with AAA. Isolated iliac aneurysms may be treated by either open or, preferentially, endovascular techniques. Intervention should be considered when the iliac diameter exceeds 3 cm. Iliac aneurysms should be repaired once the diameter exceeds 3 cm.

Level 3a, Recommendation C

- Endovascular treatment options should be considered in all patients and in defined subgroups this will include the consideration for iliac branch graft placement.

Level 3a, Recommendation C

Level 3A: systematic review (with homogeneity) of case-control studies

Recommendation C: Level 4 studies or extrapolations from level 2 or 3 studies (Extrapolations are where data are used in a situation that has potentially clinically important differences than the original study situation).

#### **Implanted Wireless Pulmonary Artery Sensor (e.g., CardioMEMS HF System) (HCPCS Codes C2624, C9741)**

Implantable intracardiac pressure monitors are intended to complement conventional drug therapy for heart failure (HF) through intermittent monitoring, allowing more timely adjustments to medications, if needed. The CardioMEMS™ HF System (St. Jude Medical, Inc., St. Paul, MN, USA, formerly Champion HF Monitoring System as well as Heart Sensor; CardioMEMS, Inc., Atlanta, GA) is a 2 x 3.4 x 15mm sized device that allows monitoring of pulmonary artery (PA) pressure using a wireless sensor. The sensor has two wire loops extending from either side. It is inserted into the PA through a traditional right heart catheterization procedure. Once deployed, PA pressure measurements can be taken repeatedly and transmitted wirelessly without requiring right heart catheterization or other invasive procedures. The sensor requires no batteries and is intended to be a permanent implant.

To record measurements at home, the patient lies on top of a pillow with sensory equipment embedded. A recording device with a cable-connected remote control is placed within four to five feet of the pillow. The patient reclines on the pillow and is guided to an optimal position by the recording device. When positioning is adequate, the machine prompts the patient to start recording by pushing the remote control. According to the manufacturer, the patient must remain still while pressures are recorded for 18 seconds, during which the machine plays music, intended to relax the patient. When the reading is complete, the machine automatically transmits the information to the CardioMEMS website (St. Jude Medical, 2014).

#### **U.S. Food and Drug Administration (FDA)**

Although a number of implantable wireless sensors are in development the CardioMEMS™ HF system is the only device in this group that has received FDA approval. On May 28, 2014 the Food and Drug Administration (FDA) granted CardioMEMS, Inc.'s (formerly Atlanta, GA, now St. Jude Medical, Inc., St. Paul, MN) premarket approval (PMA P100045) for the CardioMEMS HF System which includes the CM2000 implantable PA Sensor/Monitor and transvenous catheter delivery system, the CM1000 Patient Electronics System (GSM), the CM1010 Patient Electronics System (GSM), and CM3000 Hospital Electronics System. According to the PMA, the device is indicated for wirelessly measuring and monitoring pulmonary artery (PA) pressure and heart rate in patients with New York Heart Association (NYHA) Class III HF who have been hospitalized for HF in the previous year. The FDA approval requires that the manufacturer conduct an additional prospective, multi-center, open-label trial conducted in the United States to examine the safety and effectiveness of CardioMEMS HF System in 663 adults with NYHA Class III Heart Failure (HF) who have experienced a heart failure hospitalization within the

past 12 months; of which a total of 420 will be women. Follow-up will be two years post implant with specified safety and effectiveness endpoints. Additionally a prospective, multi-center, open-label substudy conducted in the United States to examine safety and compare the postmarket effectiveness of CardioMEMS HF System to premarket is required by the FDA.

### **Literature Review**

Data is limited in the published peer-reviewed scientific literature regarding the safety and effectiveness of the CardioMEMS HF System.

Hayes published a technology brief for wireless pulmonary artery pressure monitoring with CardioMEMS (CM) HF System for management of chronic heart failure (Hayes, 2016). The review included three clinical studies (n=12 to 550) that evaluated the accuracy, clinical utility, and safety of the CardioMEMS (CM) HF system for the management of patients with chronic heart failure. The system is a wireless implantable hemodynamic monitor (IHM) that measures pulmonary artery pressure (PAP) and heart rate in patients with heart failure (CM-IHM). Limitations of two poor-quality cohort studies included small numbers of patients, lack of data to calculate sensitivity, specificity, and predictive values, and use of echocardiography as a reference standard for diastolic PAP measurements. Although of good quality, the one randomized controlled trial was limited by a lack of data on any drug treatment modifications related to changes in patient management, and a lack of data on adverse events related to drug changes. It was found that overall, a low-quality body of evidence provides limited data suggesting that the CM-IHM system for patients with NYHA class III heart failure accurately monitors PAP, reduces heart failure-related hospitalizations through improved medical management over the first six months following implantation, and carries a minimal risk for serious adverse events.

Abraham et al. (2011) reported results of a randomized controlled trial (RCT): the CardioMEMS Heart Sensor Allows Monitoring of Pressure to Improve Outcomes in NYHA Class III Heart Failure Patients (CHAMPION) trial. The outcomes of this trial were reviewed by the FDA for premarket approval of this device. Eligible patients underwent implantation of a wireless pulmonary artery (PA) sensor monitoring system (i.e., CardioMEMS). Five hundred fifty individuals were implanted and randomized to the treatment group (n=270, standard of care HF treatment, plus PA pressure readings) or to the control group (n=280, standard of care HF treatment). Daily PA pressure readings were taken at home by patients in each group and sent to a secure website. In the treatment group clinicians had access to these readings; in the control group clinicians were unable to access pressure readings. Assessment at one, three and six months, and every six-months thereafter included a physical examination, assessment of New York Heart Association class and quality-of-life assessment by use of the 21-question Minnesota Living with Heart Failure questionnaire and review of drugs.

The primary efficacy endpoint was the rate of heart failure-related hospitalizations during the six months after insertion of the pressure sensor in the treatment group versus the control group. The two primary safety endpoints were device-related or system-related complications. The mean follow-up was 15 months. At six months 83 heart-failure-related hospitalizations were reported in the treatment group compared with 120 in the control group ( $p<0.0001$ ). During the entire follow-up (mean 15 months) the treatment group had a 39% reduction in heart-failure-related hospitalization compared with the control group ( $p<0.0001$ ). Eight patients had device- or system-related complications (DSRC). Overall freedom from DSRC was 98.6%. Overall freedom from pressure-sensor failures was 100%. Survival rates in the treatment and control groups at six months were similar ( $p=0.45$ ). Fifteen serious adverse events (AE) were reported, including, infection, bleeding, thrombosis, cardiac arrhythmias, one patient with cardiogenic shock, one atypical chest pain, and one delivery-system failure that required a snare to remove the delivery system. Data in this single clinical trial suggest improved shortterm outcomes; however, additional large blinded RCTs replicating these findings are required before use of a wireless pulmonary artery sensor monitoring system (e.g., CardioMEMS HF system) is incorporated into routine clinical practice.

### **Use Outside of the US**

National Institute of Health Care and Excellence (NICE): NICE (2013) guidance on insertion and use of implantable pulmonary artery pressure monitors in chronic heart failure notes that current evidence on the safety and efficacy of the insertion and use of implantable pulmonary artery pressure monitors in chronic heart failure is limited in both quality and quantity. They recommend that this procedure should only be used with special arrangements for clinical governance, consent and audit or research.

### **Intravascular Catheter-Based Coronary Vessel or Graft Spectroscopy (CPT Code 0205T)**

The leading cause of major morbidity and mortality is atherosclerotic cardiovascular disease, most commonly caused by thrombotic occlusion of a high-risk coronary plaque resulting in myocardial infarction or cardiac death, or embolization from a high-risk carotid plaque resulting in stroke (Alsheikh-Ali, 2010).

Near-infrared spectroscopy is proposed as a method to detect lipid and cholesterol deposits in coronary vessel walls. Ex vivo studies have demonstrated the feasibility of atherosclerotic lipid-rich plaque detection using near-infrared spectroscopy (NIRS). While near-infrared spectroscopy can collect data with rapid acquisition times, avoiding the need to obstruct blood flow it does not create an image of the vessel wall, which is a limitation of the device. Fibroatheromas that are thick capped or too small to be defined as lipid core plaques are major sources of false-positive readings (Alsheikh-Ali, 2010).

### **U.S. Food and Drug Administration (FDA)**

The LipiScan Coronary Imaging System (InfraReDx, Inc., Burlington, MA) received FDA 510(k) approval in April 2008. The device is indicated for the near-infrared examination of coronary arteries.

### **Literature Review**

Randomized controlled clinical trial data are lacking in the published peer-reviewed scientific literature. Waxman et al. (2009) reported initial results of the first-in-human uncontrolled validation study involving a catheter-based near-infrared spectroscopy system for the detection of lipid core coronary plaques (SPECTACL [SPECTroscopic Assessment of Coronary Lipid] trial). A total of 106 patients were enrolled in the study, spectroscopic data was obtained in 89 patients. Spectral similarity was demonstrated in 83% of available patients. The algorithm developed ex vivo identified the high-risk plaques in 60% of imaged segments in patients undergoing percutaneous coronary intervention. The authors note the feasibility of invasive detection of coronary lipid core plaques with this system.

### **Professional Societies/Organizations**

Guidelines from the American Heart Association and the American College of Cardiology do not include guidance regarding use of intravascular catheter-based coronary vessel or graft spectroscopy to identify lipid core plaques or for any indication.

#### **Use Outside of the US**

No relevant information.

#### **Acoustic Cardiography (CPT code 93799)**

Acoustic cardiography, also referred to as correlated audioelectric cardiography is a noninvasive diagnostic tool designed to be used in the evaluation of cardiac conditions such as left ventricular hypertrophy (LVH), acute and age-undetermined myocardial infarction (MI), cardiac arrhythmias, and detection of S3 and S4 heart sounds. An S3 heart sound may be associated with heart failure in patients over age 40. Acoustic cardiography is intended to augment physician auscultation, since S3 and S4 heart sounds may be difficult to hear in some patients. The device acquires, displays, and analyzes 12-lead electrocardiogram (ECG) and heart sound data (Collins et al., 2006; Kobza et al., 2008; Wagner et al., 2002; Warner et al., 2002).

Traditional diagnostic methods include physical examination and auscultation, 12-lead ECG laboratory examinations, measurement of biomarkers of cardiac damage, and imaging.

#### **U.S. Food and Drug Administration (FDA)**

The Eli 200+ Audicor (Mortara Instrument, Inc., Milwaukee, WI) is an interpretive electrocardiograph device designed to acquire, record and store cardiac data. The device uses Audicor Correlated Audioelectric Cardiography (COR) technology (Inovise Medical, Inc., Newberg, OR) to simultaneously acquire both 12-lead electrocardiogram (ECG) and heart sound data. The Eli 200+ Audicor received U.S. Food and Drug Administration (FDA) clearance to market as a Class II device through the 510(k) process on July 25, 2003. The device was considered a technology evolution and substantially equivalent to the ELI 200, Inovise's Cardiovisc Interpretive Software, and Hewlett Packard's 1514A ECG/Phono System.

The FDA 510(k) notification of clearance to market the Eli 200+ Audicor included the following indications for use:

- The device is indicated for use to acquire, analyze, display and print ECG and heart sound data (COR).
- The device is indicated for use to provide interpretation of the data for consideration by physicians.
- The device is indicated for use in a clinical setting by a physician or by trained personnel and is not intended as a sole means of diagnosis.
- The interpretations of ECG and heart sound data (COR) offered by the device are only significant when used in conjunction with physician over-read as well as consideration of all other relevant patient data.
- The device is intended for use on adult populations, typically symptomatic.
- The device is not intended to be used as a vital signs physiological monitor.

- The device is indicated for evaluation of cardiac conditions such as left ventricular hypertrophy (LVH), acute and age-undetermined myocardial infarction (MI), and detection of S3 and S4 heart sounds.

On October 31, 2003, the Audicor Upgrade System received FDA clearance as a Class II device through the 510(k) process. The Audicor Upgrade System is an add-on device used with Audicor Sensors in the V3 and V4 positions on the chest wall. The system consists of a pocket personal computer (PC) with proprietary software and can be used with several models of existing electrocardiographs to allow physicians access to the COR report, including graphical display of MI and LVH conditions, display of heart sound waveforms, and identification of S3 and S4 heart sounds.

The Zargis Acoustic Cardioscan (Zargis Medical Corporation, Princeton, NJ) received FDA approval through the 510(k) process on May 26, 2004. The system is an electronic auscultatory device intended to acquire, record, and analyze heart sounds. The system consists of an electronic stethoscope, notebook computer, software, printer and an isolation transformer. According to the FDA indications for use, the device acquires and records the acoustic signals of the heart and analyses these signals. The analysis procedure will identify specific heart sounds that may be present, including S1, S2, and suspected murmurs. The approval lists the Audicor system as a predicate device.

### Literature Review

Published studies have evaluated the use of Cardiovisc diagnostic software, a predicate device and component of the Audicor System, for the detection of acute and prior MI (Wagner, et al., 2002; Andresen, et al., 2002). Published studies involving the Audicor system or correlated audioelectric cardiography are limited.

Wang reported on results of a prospective cohort study of 474 patients with heart failure (HF) to evaluate whether acoustic cardiography can identify HF patients at high risk for mortality. Acoustic cardiographic parameters included S3 score and systolic dysfunction index (SDI) (correlated closely with left ventricular systolic dysfunction). The event-free survival curves were plotted by Kaplan-Meier method and Cox regression analysis was used to identify independent predictors for all-cause mortality. With a mean follow-up of 484 days, 169 (35.7%) patients died and 126 (26.6%) were due to cardiac causes. After controlling for age, systolic blood pressure, hemoglobin, blood urea nitrogen, albumin, as well as ACEI and beta-blocker treatment in multivariate Cox regression analysis, SDI  $\geq 5$  and S3 score  $\geq 4$  were both independent predictors for all-cause mortality. Kaplan-Meier analysis showed that HF patients with SDI  $\geq 5$  or S3 score  $\geq 4$  had a significantly lower survival (52.2% vs. 69.2%, Log-rank  $\chi^2=18.07$ ,  $P<0.001$ ; 56.8% vs. 68.6%, Log-rank  $\chi^2=10.58$ ,  $P=0.001$ , respectively) than those with lower SDI or S3 score. The study was limited by the lack of randomization. Limitations noted in the study included that adverse nonfatal outcomes including rehospitalization or severe medical complications were not evaluated in this study and further investigations focusing on prediction of subsequent cardiovascular events are warranted; BNP was not routinely measured in heart failure patients and not included as biomarker in the analysis; and, heart failure patients with atrial fibrillation were not excluded from our study.

Wang et al. (2013) reported the results of a prospective cohort study ( $n=272$ ) to determine the diagnostic utility of acoustic cardiography in patients with heart failure (HF). Cohort subjects had hypertension ( $n=94$ ), heart failure (HF) and normal ejection fraction (HRNEF,  $n=109$ , EF $\geq 50\%$ ) and HF and reduced EF (HRREF,  $n=89$ , EF $<50\%$ ). All participants received acoustic cardiography and echocardiography examinations. Acoustic cardiographic parameters included S3 score, electromechanical activation time (EMAT) and systolic dysfunction index (SDI). EMAT significantly differentiated HFNEF from hypertension (area under curve [AUC], 0.83; 95% confidence interval [CI], 0.77–0.89) with a sensitivity and specificity of 55% and 90%, respectively. An echocardiogram yield a sensitivity of 55% and 90% specificity. An SDI $>5.43$  yielded 53% sensitivity and 91% specificity. The authors note that this technology may be helpful in identifying HF and its phenotypes when echocardiography is not available. The study is limited by small size, uncontrolled design and low sensitivity and specificity results.

Collins et al. (2009) conducted a multisite study to evaluate the effect of an S3 captured by acoustic cardiography on diagnostic accuracy and confidence in the diagnosis of acute decompensated heart failure in patients presenting to the emergency department (ED) with dyspnea ( $n=995$ ). The study also evaluated the impact on patient prognosis. ED physicians who were initially blinded to all laboratory and acoustic cardiography results estimated the probability of acute decompensated heart failure on a scale of 0% to 100% on a visual analog scale. The visual analog scale was repeated after acoustic cardiography results were provided. Patients

were followed for 90 days to determine the relationship of the S3 to adverse events. The initial sensitivity, specificity, and accuracy for acute decompensated heart failure as a possible diagnosis were 89.0%, 58.2%, and 71.0%, respectively. Sensitivity, specificity, and accuracy for acoustic cardiography were 40.2%, 88.5%, and 68%, respectively. The authors concluded that acoustic cardiography S3 was specific to acute decompensated heart failure, but did not improve diagnostic accuracy, primarily because of the low sensitivity. In addition, the acoustic cardiography S3 provided no significant independent prognostic information.

Maisel et al. (2011) conducted a secondary analysis of the Collins study (2009) to determine if the strength of the S<sub>3</sub> can provide diagnostic prognostic information in problematic heart failure subgroups. The analysis included dyspneic ED patients older than age 40 who were not on dialysis. A gold standard acute heart failure diagnosis was determined by two cardiologists who were blinded to acoustic cardiography results. In the 995 enrolled patients, S<sub>3</sub> strength was a significant prognosticator in univariate analysis for adverse events. When results were incorporated into the multivariable analysis in stepwise fashion, however, it was not as predictive as other variables, such as B-type natriuretic peptide (BNP) values and ST-depression on ECG. In the subgroup of patients with "gray zone" BNP levels, acoustic cardiography increased diagnostic accuracy of acute heart failure (AHF) from 47% to 69%. Acoustic cardiography also improved S<sub>3</sub> detection sensitivity in obese patients compared to auscultation. The authors stated that although acoustic cardiography appears to augment the use of BNP, particularly in problematic subgroups, there were limitations to the study, including the fact that the true diagnostic characteristics when used in real time are unknown, due to the retrospective nature of the study and limited data availability. In addition, cardiologists making the AHF diagnosis were not blinded to BNP results, which would have impacted the diagnosis.

Kobza et al. (2008) conducted a case series (n=57), to evaluate the use of acoustic cardiography using the Audicor device) during electrophysiological (EP) testing for known or suspected cardiac arrhythmias concluding that acoustic cardiography is useful for identifying VT and may facilitate the differential diagnosis of clinically important tachyarrhythmias, particularly when advanced techniques such as EP studies are not available.

Collins et al. (2006) evaluated the use of an S3 heart sound combined with B-type natriuretic peptide (BNP) levels in the diagnosis of emergency room patients with dyspnea (n=439). The author concluded that an S3 sound is highly specific for heart failure and is ideally suited for use in combination with BNP to improve diagnostic accuracy. The sensitivity, specificity, positive and negative predictive value, and diagnostic accuracy of the electronic S3 for primary heart failure were 34%, 93%, 66%, 7%, and 70%, respectively. The values obtained by physician auscultation were 16%, 97%, 84%, 3%, and 66%, respectively. The addition of an Audicor S3 to intermediate BNP levels improved the positive likelihood ratio from 1.3 to 2.9 and improved the positive predictive value from 53% to 80%. The overall ER misdiagnosis rate was 14%. Of the 48 cases, 44 were a failure to diagnose heart failure when it was present. If the Audicor had been used as the sole diagnostic tool among these 44 ultimately considered to have primary HF, 15 would have been correctly diagnosed. Similarly, if the Audicor tool had been used as the sole diagnostic tool, 14 of the 206 patients correctly diagnosed as nonprimary HF would have been incorrectly diagnosed as primary HF. Although the evaluation of S3 heart sounds in combination with BNP testing may improve diagnostic accuracy in patients with dyspnea of unclear etiology, this study does not demonstrate that the Audicor system provides a benefit, when used alone or in combination with other tests, in terms of improved clinical outcomes.

Marcus et al. (2006) conducted a prospective study to determine the diagnostic test characteristics of the S3 and S4 heart sounds for prediction of left ventricular dysfunction using the Audicor system in patients undergoing elective left-sided heart catheterization (n=90). Patients underwent computerized heart sound phonocardiographic analysis (Audicor system) for assessment of S3/S4 heart sounds, cardiac catheterization for assessment of left ventricular end-diastolic pressure (LVEDP), transthoracic echocardiography for evaluation of left ventricular ejection fraction (LVEF), and blood sampling for BNP. Mean LVEDP was significantly elevated; LVEF was reduced; and median BNP was elevated in those with an S3, S4, or both, compared to patients without a diastolic heart sound. The sensitivities of these heart sounds to detect an elevated LVEDP, reduced LVEF, or elevated BNP were 41%, 52%, 32% for an S3, and 46%, 43%, and 40% for an S4, respectively. The authors concluded that neither the phonocardiographic S3 nor the S4 is a sensitive marker of left ventricular dysfunction. The absence of an S3 or S4 using phonocardiographic testing (Audicor system) is therefore not sufficient to exclude ventricular dysfunction. If present, the phonocardiographic S3 and S4 are specific for an elevated LVEDP, depressed LVEF, and elevated BNP level.

## Professional Societies/Organizations

**American College of Cardiology/American Heart Association (ACC/AHA):** ACC/AHA Guidelines for the Management of Patients with ST-Elevation Myocardial Infarction (O'Gara, et al., 2013) and the ACC/AHA Guideline Update for the Diagnosis and Management of Chronic Heart Failure in the Adult (Yancey, et al., 2013), do not include the use correlated audioelectric cardiography or acoustic heart sounds as a diagnostic tool. In addition, this technology is not mentioned in AHA/ACC Recommendations for the Standardization and Interpretation of the Electrocardiogram, Part I (Kligfield, et al., 2007) and II (Mason, et al., 2007).

**American Heart Association (AHA):** The AHA scientific statement, Acute Heart Failure Syndromes: Emergency Department Presentation, Treatment, and Disposition: Current Approaches and Future Aims, includes a discussion of focused areas for future investigation. The authors note that the search for additional tools to improve the diagnostic accuracy for patients with undifferentiated dyspnea and possible acute heart failure syndromes remains a high priority. Electronic detection of third heart sounds (S<sub>3</sub>) using acoustic cardiography is included among several tools that have been investigated as both stand-alone and adjunct diagnostic measures, but appear to provide little benefit over existing approaches (Weintraub et al., 2010).

## Use Outside of the US

**Australian and New Zealand Horizon Scanning Network ([ANZHSN], 2010):** A Horizon Scanning Technology Prioritizing Summary notes that although comparative evidence indicated that the adjunctive use of acoustic cardiography may be of benefit in the diagnosis of heart failure, the application of this technology in the acute setting was considered impractical.

#### **Transluminal Peripheral Atherectomy (CPT Codes 0234T, 0235T, 0236T, 0237T, 0238T)**

Peripheral artery disease (PAD) broadly encompasses the vascular diseases caused primarily by atherosclerosis and thromboembolic pathophysiologic processes that alter the normal structure and function of the aorta, its visceral arterial branches, and the arteries of the lower extremity (American College of Cardiology Foundation [ACCF]/American Heart Association [AHA], 2011). PAD may be treated medically, and with angioplasty and stenting for patients not responding to medical treatment. Atherectomy involves the removal of plaque burden using physical or ablative means (e.g., laser) in a directional (proximal to distal, usually) or rotational manner and may or may not be combined with angioplasty and stenting (Zaetta, et al. 2017). Atherectomy may be used in the atherectomy of femoral, popliteal artery and tibial, peroneal artery. It has been proposed to be used in the treatment of in arteries above the inguinal ligaments (renal, visceral, abdominal aorta, brachiocephalic trunk and branches and iliac artery).

#### **Literature Review**

The medical literature has shown atherectomy to be both safe and effective in femoro-popliteal and infrapopliteal segments. The published peer reviewed scientific literature is preliminary and limited for atherectomy in arteries above the inguinal ligaments (renal, visceral, abdominal aorta, brachiocephalic trunk and branches and iliac artery) and mainly involves small retrospective studies of procedures involving iliac artery.

Valle et al. (2017) reported on a case study of orbital atherectomy in the renal vasculature. A retrospective, uncontrolled, single-center study (Thatipelli, et al., 2009) evaluated the safety and efficacy of blunt microdissection in patients with symptomatic CTOs of the pelvis and lower extremities. Follow-up data were available for up to 1 year. The study included 61 patients who underwent 67 procedures in 86 arteries. The target lesion was located in the aortoiliac artery in 11 of 87 segments (13%), femoropopliteal artery in 72 (83%), and infrapopliteal artery in 4 (5%). All had severe claudication, rest pain, or tissue loss. The authors concluded that this treatment is safe and efficacious, but also noted that the results, drawn from a group of patients referred

to a tertiary center, may not be applicable to the general population of patients with PAD. Furthermore, the follow-up data are incomplete since a high number of cases were not included, which limits the ability to determine the actual rates of treatment success.

### **Professional Societies/Organizations**

**American College of Cardiology Foundation/American Heart Association ([ACCF/AHA], 2011):** The ACCF/AHA published a guideline titled, Management of Patients with Peripheral Artery Disease (Lower Extremity, Renal, Mesenteric, and Abdominal Aortic), which is adapted from the 2005 ACCF/AHA Guideline and the 2011 ACCF/AHA focused update. Regarding endovascular treatment of claudication the Guideline notes:

- Class IIa, Level of Evidence C recommendation notes that stents (and other adjunctive techniques such as lasers, cutting balloons, atherectomy devices, and thermal devices) can be useful in the femoral, popliteal, and tibial arteries as salvage therapy for a suboptimal or failed result from balloon dilation (e.g., persistent translesional gradient, residual diameter stenosis >50%, or flow limiting dissection).
- Class IIb, Level of Evidence A recommendation notes that the effectiveness of stents, atherectomy, cutting balloons, thermal devices, and lasers for the treatment of femoral-popliteal arterial lesions (except to salvage a suboptimal result from balloon dilation) is not well established.
- Class IIb, level of evidence C recommendation notes that the effectiveness of uncoated/uncovered stents, atherectomy, cutting balloons, thermal devices, and lasers for the treatment of infrapopliteal lesions (except to salvage a suboptimal result from balloon dilation) is not well established."

Definitions regarding class and level of evidence ratings are as follows:

Class IIa, Level of Evidence: A: Benefit >>Risk. Additional studies with focused objectives needed. It is reasonable to perform procedure/administer treatment, recommendation in favor of treatment or procedure being useful/effective, some conflicting evidence from multiple randomized trials or meta-analyses;

Class IIb, Level of Evidence: A: Benefit ≥ Risk. Additional studies with broad objectives needed; additional registry data would be helpful. Procedure/Treatment may be considered. Recommendation's usefulness/efficacy less well established, greater conflicting evidence from multiple randomized trials or meta-analyses;

Class IIb, Level of Evidence: C: Benefit ≥ Risk. Additional studies with broad objectives needed; additional registry data would be helpful. Procedure/Treatment may be considered. Recommendation's usefulness/efficacy less well established. Only diverging expert opinion, case studies, or standard of care.

### **Use Outside of the US**

**European Stroke Organisation/European Society of Cardiology (ESC):** In a practice guideline on the diagnosis and treatment of peripheral artery diseases, these organizations states that atherectomy devices have unclear long-term benefits and that aortoiliac or bifemoral bypass is usually recommended for diffuse aortoiliac disease. Owing to the limited probability of improvement in symptoms with exercise therapy in the case of aortoiliac lesions, revascularization should be considered without initial conservative treatment. Surgery is limited to extensive lesions without the possibility for endovascular treatment. In patients with disabling intermittent claudication that impacts their activities of daily living, with culprit lesions located at the aorta/iliac arteries, revascularization (endovascular or surgical) should be considered as the first choice therapeutic option. In the external iliac arteries, a primary stenting strategy using self-expandable stents is preferred over provisional stenting, mainly due to a lower risk of dissection and elastic recoil (European Stroke Organisation/ESC 2011).

#### **Near-Infrared Guidance for Vascular Access Requiring Real-Time Digital Visualization for Evaluation of Potential Access Sites and Vessel Patency (CPT Code 99199)**

A peripheral venous catheter is most commonly used for venous access. Traditional techniques for determining the location of a peripheral vein includes palpating the skin, and unaided visualization of the skin in ambient light (Perry, 2011). Use of a near-infrared imaging system has been proposed as an alternative method to aid in visualization of the superficial vasculature. The imaging system provides a display of peripheral vasculature in real-time. It is purported to reduce the number of intravenous (IV) attempts, reduce the time it takes to initiate an IV and improve patient satisfaction (Christie Medical, 2013).

**U.S. Food and Drug Administration (FDA):** The VTS1000 Liquid Crystal Vein Locator (VueTek Scientific™, LLC, Gray, MN) received 510 (k) approval on Feb 18, 2011. The VTS1000 is a noninvasive electronic device to aid in the visualization of superficial vasculature. According to the 510(k) summary it is indicated for use during procedures requiring vascular or peripheral vascular access.

#### **Literature Review**

Rothbart et al. (2015) reported on a retrospective study of that examined the use of Accuvein® AV300 vein viewer used to facilitate venous cannulation in children. The study included 238 consecutive pediatric patients preceding surgical interventions. The subjects were allocated to groups [control group (124 patients) and intervention group (114 patients)] in a non-random way - randomization was not feasible because data was acquired retrospectively. In control group, peripheral IV cannulation was performed without supporting device, in intervention group with support of AV300. Time and number of attempts until successful venous cannulation were defined as primary end points. The study found that the median time until successful cannulation was 2 min (range 0.1-20, quartiles: 25%: 1; 75%: 5) in the intervention group and 1 min (range 0.1-18, quartiles: 25%: 0.2; 75%: 2) in the control group ( $p < 0.01$ ). Median number of attempts was higher in the intervention group (2; range 1-6, quartiles: 25%: 1; 75%: 3) than in the control group (1; range 1-6, quartiles: 25%: 1; 75%: 2,  $p < 0.01$ ). the rate of cannulations successful at first attempt was 0.45 (51 of 114, 95% CI 0.35-0.54) in the intervention group and 0.73 (90 of 124, 95% CI 0.65-0.81) in the control group ( $p < 0.01$ ). the authors concluded that they were not able to reduce neither time nor number of attempts until a successful venous cannulation in children using the vein viewer and that laser-supported cannulation cannot be recommended for standard procedures. The study was limited with the lack of randomization.

Van der Woude et al. (2013) reported results of a pragmatic cluster randomized controlled clinical trial using the VascuLuminator in a population of children with dark skin color requiring intravenous (IV) cannulation in the operating room. Eighty-eight patients were included in the study (control, n=45; VascuLuminator, n=43). The

availability of the VascuLuminator to anesthesiologists at the operating complex was randomized by computer in clusters of one week. In the VascuLuminator group IV cannulation was aided by the device, whereas the device was not available at the operating room in the control group. Success at first attempt was not significant between the two groups ( $p=0.27$ ). Median time to successful cannulation was not significant between groups ( $p=.54$ ). In the subgroup of children a priori anticipated to be difficult to cannulate (i.e., "hard" or "very hard"), there was a trend to higher success at first attempt in the VascuLuminator group ( $p = 0.03$ ). The authors noted data suggest limited value of the VascuLuminator in facilitating IV cannulation in a subgroup of children with dark skin color who are anticipated to be difficult to cannulate.

Kim et al. (2012) evaluated a group of 111 children who were randomized into one of the two groups (VeinViewer,  $n=54$ ) or control ( $n=57$ ). There was no significant difference in the overall first attempt success rate using the VeinViewer compared with control ( $p=0.526$ ). There was no significant difference between the groups for easy ( $p=0.485$ ), or difficult patients ( $p=.0026$ ). Limitations to the study cited by the authors included that the procedural time was analyzed only in patients with successful venous access on the first attempt because the time interval after the first failed attempt varied according to the operator and the situation. Further, the amount of training and practice to attain proficiency with the VeinViewer has not been established.

Phipps et al. (2012) randomized 115 preterm and term neonates undergoing placement of peripherally inserted central catheters by use of VeinViewer ( $n=59$ ) or standard techniques ( $n=56$ ). Overall, there was a trend to more successful placement using VeinViewer, but no statistical significance ( $p=0.08$ ). When analysis was limited to the first attempt at cannulation no differences between the two techniques were found ( $p=0.55$ ). Additionally, infants randomized to the VeinViewer were more mature ( $30\pm 2$  weeks gestational age (GA) versus  $28\pm 2$  weeks GA;  $p=0.08$ ). Study limitations included lack of blinding regarding use of VeinViewer compared with standard techniques. Larger studies are needed to demonstrate the effectiveness of this device over standard techniques for attaining peripheral venous access.

Chapman et al. (2011) reported results of a prospective, randomized study of children aged 0 to 17 who required nonemergent peripheral intravenous (PIV) catheter placement. Participants were randomized to standard PIV cannulation or PIV cannulation with the VeinViewer (Christie Medical Holdings, Cypress, CA, formerly Luminetx, Memphis, TN). The primary outcome measure was time to PIV placement. Secondary outcome measures included number of PIV attempts and pain scores as reported by the child, parent or guardian and nurse. A total of 323 patients completed the study. No differences in time to PIV placement, number of PIV attempts or pain scores was noted for the overall study group. However, a planned subgroup analysis of children aged 0 to 2 ( $n=107$ ) did yield significant results for time to PIV placement ( $p<0.047$ ), and for nurses' perception of pain ( $p=0.01$ ). Data did not support improvement in outcomes for the total study group. Additional randomized controlled trials (RCT) should be conducted to determine the role of this device for evaluation of potential access sites.

Perry et al. (2011) conducted a prospective RCT to determine whether the use of a near-infrared light venipuncture aid (VeinViewer, Christie Medical Holdings, Cypress, CA, formerly Luminetx, Memphis, TN) would improve the rate of successful first-attempt placement of intravenous (IV) catheters in a high-volume pediatric emergency department (ED). One hundred twenty-three patients were randomized to use of the device ( $n=62$ ) or the traditional technique of palpation of the overlying skin and unaided visualization of peripheral veins for IV access using only ambient room light ( $n=61$ ). If a vein could not be cannulated after three attempts, patients crossed over from one study arm to the other, and study nurses attempted placement with the alternative technique. The primary end point was first-attempt success rate for intravenous (IV) catheter placement. After completion of patient enrollment, a questionnaire was completed by study nurses as a qualitative assessment of the device. There was no significant difference in first-attempt success rate between the standard and device groups. Of the 19 study nurses, 14 completed the questionnaire. Seventy percent expressed neutral or unfavorable assessments of the device in nondehydrated patients. Ninety percent of nurses found the device a helpful tool for patients in whom IV access was difficult. Additional RCTs with large patient populations should be conducted to demonstrate the role of the device in these patients.

## **Intravascular Optical Coherence Tomography (OCT) (Coronary Native Vessel or Graft) (CPT Codes 92978, 92979)**

Invasive coronary angiography is considered the gold standard for evaluating patients with suspected myocardial ischemia. Intracoronary optical coherence tomography (OCT) is an intravascular imaging technique performed during cardiac catheterization that measures the echo time delay and intensity of backscattered light from tissue's internal microstructure. This diagnostic procedure creates high-resolution, cross-sectional images of the coronary arteries to permit quantification of lumen dimensions and the extent of lumen narrowing, visualization of atherosclerotic plaque, and characterization of the structure and extent of plaque.

OCT systems comprise a fiberoptic imaging catheter attached to a patient interface unit, which connects to a system console. The console contains an optical engine (i.e., light source, beam splitter, reference arm, detectors, signal processor) and a computer that collects multiple light signals reflected from different tissue depths and combines them to make a three-dimensional image. Signal intensity is mapped to a color space that is displayed on a monitor.

OCT is frequently compared to intravascular ultrasound (IVUS). Compared to IVUS, it is purported that OCT provides enhanced contrast between lumen and vessel walls, higher axial resolution of intracoronary plaque structures, and faster pullback. OCT catheters are smaller in diameter than IVUS catheters, allowing safer image acquisition from smaller-caliber vessels (St. Jude Medical, 2012).

The major limitation of OCT is its inability to consistently image the outer layer of the vessel wall and assess plaque burden due to limited tissue penetration (1.0 to 1.5 mm). Also, using OCT to measure large-diameter vessels at proximal target sites may be difficult, and the manufacturer has indicated that aorto-ostial lesions are not suitable for OCT imaging.

**U.S. Food and Drug Administration (FDA):** Several intracoronary optical coherence tomography products made by St. Jude Medical, Inc., (St. Paul, MN), have received FDA 510 (k) approval. These include the C7 XR Imaging system (April 2010) and the C7 Dragonfly Intravascular Imaging catheter and disposable accessories (April, 2010). Others include the ILUMIEN System, (LightLab Imaging, Inc., Westford, MA, July 2011) and the OCT Imaging system and catheter (Volcano Corporation (San Diego, CA) received 510(k) approval on Jan, 2010).

## Literature Review

Although there are a number of prospective and retrospective studies and review articles in the published peer-reviewed scientific literature, randomized controlled trial data are lacking to inform health outcomes as a result of intracoronary optical coherence tomography. A number of clinical trials are ongoing.

Ali et al (2016) reported on a randomized controlled trial that examined whether or not a novel OCT-based stent sizing strategy would result in a minimum stent area similar to or better than that achieved with IVUS guidance and better than that achieved with angiography guidance alone. The primary efficacy endpoint was post-PCI minimum stent area, measured by OCT at a masked independent core laboratory at completion of enrolment, in all randomly allocated participants who had primary outcome data. The primary safety endpoint was procedural major adverse cardiovascular events (MACE). The study randomly allocated 450 patients (158 [35%] to OCT, 146 [32%] to IVUS, and 146 [32%] to angiography), with 415 final OCT acquisitions analyzed for the primary endpoint (140 [34%] in the OCT group, 135 [33%] in the IVUS group, and 140 [34%] in the angiography group). The final median minimum stent area was 5.79 mm<sup>2</sup> (IQR 4.54-7.34) with OCT guidance, 5.89 mm<sup>2</sup> (4.67-7.80) with IVUS guidance, and 5.49 mm<sup>2</sup> (4.39-6.59) with angiography guidance. OCT guidance was non-inferior to IVUS guidance (one-sided 97.5% lower CI -0.70 mm<sup>2</sup>; p=0.001), but not superior (p=0.42). OCT guidance was also not superior to angiography guidance (p=0.12). Procedural MACE was noted in four (3%) of 158 patients in the OCT group, one (1%) of 146 in the IVUS group, and one (1%) of 146 in the angiography group (OCT vs IVUS p=0.37; OCT vs angiography p=0.37). The authors concluded that OCT using a specific reference segment external elastic lamina-based stent optimization strategy was safe and resulted in similar minimum stent area to that of IVUS-guided PCI, however the results warrants a large-scale randomized trial to establish whether or not OCT guidance results in superior clinical outcomes to angiography guidance.

Meneveau et al. (2016) reported on a multicenter, randomized study involving 240 patients with non-ST-segment elevation acute coronary syndromes to compare OCT-guided PCI (use of OCT pre- and post-PCI; OCT-guided group) to fluoroscopy-guided PCI (angiography-guided group). The primary end point was the functional result of PCI assessed by the measure of post PCI fractional flow reserve. The secondary end points included procedural complications and type 4a peri-procedural myocardial infarction and safety was assessed by the rate of acute kidney injury. Findings included that OCT use led to a change in procedural strategy in 50% of the patients in the OCT-guided group. The primary end point was improved in the OCT-guided group, with a significantly higher fractional flow reserve value (0.94±0.04 versus 0.92±0.05, P=0.005) compared with the angiography-guided group. There was no significant difference in the rate of type 4a myocardial infarction (33% in the OCT-group versus 40% in the angiography-guided group, P=0.28). The rates of procedural complications (5.8%) and acute kidney injury (1.6%) were identical in each group despite longer procedure time and use of more contrast medium in the OCT-guided group. Post-PCI OCT revealed stent under-expansion in 42% of patients, stent malapposition in 32%, incomplete lesion coverage in 20%, and edge dissection in 37.5%. This led to the more frequent use of post-stent overdilation in the OCT-guided group versus the angiography-guided group (43% versus 12.5%, P<0.0001) with lower residual stenosis (7.0±4.3% versus 8.7±6.3%, P=0.01). The authors concluded that in patients with non-ST-segment elevation acute coronary syndromes, OCT-guided PCI is associated with higher post-procedure fractional flow reserve than PCI guided by angiography alone. The procedure did result in longer procedure time, but did not increase peri-procedural complications, type 4a myocardial infarction, or acute kidney injury.

Hayes published a directory report for optical coherence tomography (OCT) for plaque characterization and stent implantation (Hayes, 2016). The review included 19 studies, including 8 prospective and 5 retrospective uncontrolled or noncomparative cohort studies; one retrospective comparative cohort study; one prospective, case-matched cohort study; two retrospective, case-matched cohort or cross-sectional studies; and two randomized controlled trials (RCTs). The review noted that reviewed studies provide consistent evidence that OCT can detect features of plaques and stents that are associated with increased risk of adverse cardiac events. However, the reviewed studies do not provide sufficient evidence to conclude that the information obtained with OCT can be used to improve patient management and reduce the risk associated with adverse plaque and stent characteristics, particularly relative to guidance of percutaneous coronary interventions (PCI) with intravascular ultrasonography (IVUS). Additional well-designed studies are needed to determine whether guidance of PCI with OCT and angiography improves patient outcomes versus guidance with IVUS and angiography or with angiography alone.

#### **Professional Societies/Organizations**

##### **American College of Cardiology Foundation, American Heart Association, and Society for**

**Cardiovascular Angiography and Interventions Association Task Force:** These Societies published a joint practice guideline titled, Percutaneous Coronary Intervention (Levine, et al., 2011). The guideline notes that

compared with IVUS, optical coherence tomography has greater resolution (10 to 20 micronmeter axially) but more limited depth of imaging (1 to 1.5 mm). Unlike IVUS, optical coherence tomography requires that the artery be perfused with saline solution or crystalloid during image acquisition and therefore does not permit imaging of ostial lesions. Clinical studies have shown low optical coherence tomography complication rates, similar to those of IVUS. The excellent resolution of optical coherence tomography permits detailed in vivo 2-dimensional imaging of plaque morphological characteristics (e.g., calcification, lipid, thrombus, fibrous cap thickness, and plaque ulceration or rupture) and evaluation of the arterial response to stent implantation (e.g., stent strut neointimal thickness and apposition) and may be of value in clinical research. The practice guideline notes the appropriate role for optical coherence tomography in routine clinical decision making has not been established.

### **Use Outside of the US**

**The Task Force on Myocardial Revascularization of the European Society of Cardiology and the European Association for Cardio-Thoracic Surgery:** These Societies published joint Guidelines on Myocardial Revascularization in 2010. These guidelines note that OCT is a light-based modality of intravascular imaging with higher spatial resolution than intravascular ultrasound (15µm vs. 100µm). Its penetration is lower than intravascular ultrasound but it provides detailed imaging of the endoluminal borders. At present, OCT is a valuable research tool.

### **Endothelial Function Assessment (CPT Code 0337T)**

The endothelium helps to regulate vascular tone, cellular adhesion, thromboresistance, smooth muscle cell proliferation, and vessel wall inflammation. Alteration in endothelial function precedes the development of morphological atherosclerotic changes and can also contribute to lesion development and later clinical complications (Deanfield, 2007). Noninvasive endothelial function assessment has been proposed as a means to predict the risk of atherosclerosis and cardiovascular disease.

One method involves measurement of the brachial diameter before and after an increase in shear stress induced by reactive hyperemia or flow-mediated dilation (FMD). Special probes that have pneumoelectrical tubing that connect to a computer are placed in an arm stabilizer and the index finger is placed in a probe. A

sphygmomanometer cuff is placed on the forearm distal to the brachial artery, inflated and released for a timed period. This is repeated with higher pressures used to mimic occlusion. Finally the pressures are measured five minutes after the pressure is released. FMD occurs as a result of local endothelial release of nitrous oxide. The information is evaluated by proprietary software and a score indicating the endothelial health is generated. Digital peripheral arterial tonometry (PAT) quantifies reactive hyperemia-induced changes in pulse volume amplitude (PVA) in the finger tip, and is an automated method to non-invasively assess endothelial function (Lee, 2012). According to the manufacturer, EndoPAT™ measures several vascular beds, composed of small vessels and microcirculation. The manufacturer also notes the EndoPAT™ corrects for systemic changes by a simultaneous measurement from the (un-occluded) contra-lateral arm.

**U.S. Food and Drug Administration (FDA):** The Endo PAT 2000 device (Itamar Medical, Inc., Framingham, MA) received 510(k) approval in November 2003. According to the approval summary it is a non-invasive device, intended for use as a diagnostic aid in the detection of coronary artery endothelial dysfunction (positive or negative) using a reactive hyperemia procedure. The summary also notes “The Endo PAT 2000 has been shown to be predictive of coronary artery endothelial dysfunction in the following patient population: patients with signs or symptoms of ischemic heart disease, who are indicated for coronary artery angiography, but who lack angiographic evidence of obstructive coronary artery disease. The device is intended to be used in a hospital or clinic environment by competent health professionals. The Endo PAT 2000 device is not intended for use as a screening test in the general patient population. It is intended to supplement, not substitute, the physician’s decision-making process. It should be used in conjunction with knowledge of the patient’s history and other clinical findings.”

The CVProfilor® System, Cardiovascular Profiling System, original applicant Hypertension Diagnostics, Inc. (Eagan, MN) received 510(k) approval (K001948) from the FDA in November, 2000 as a Class II device for the noninvasive measurement of blood pressure and pulse rate. According to the summary “It is classified as a noninvasive blood pressure measurement system providing a signal from which systolic, diastolic, mean, or any combination of the three pressures can be derived through the use of transducers placed on the surface of the body.”

### Literature Review

Randomized controlled clinical trial data are lacking to demonstrate the clinical utility and effectiveness of endothelial function assessment to predict cardiovascular risk. The majority of studies in the published peer-reviewed literature are prospective cohorts.

Hayes published a technology directory report on peripheral arterial tonometry (PAT), a noninvasive device intended for the evaluation of endothelial dysfunction using indirect measurement of induced reactive hyperemia (RH) (Hayes, 2014; 2015; 2016). The review included ten peer-reviewed cross-sectional or prospective cohort studies evaluating RH-PAT, with sample size of 60 to 238 patients. Six studies investigated RH-PAT for: detecting coronary endothelial dysfunction in patients without CAD (one study), for detecting myocardial ischemia in a RH-PAT exercise test (one study), and for detecting or characterizing CAD (four studies). Four studies investigated RH-PAT for predicting cardiovascular adverse events following a surgical procedure. The results varied across studies and applications due to heterogeneity in patient selection criteria, applications, reference standards, and cut-off values. There were no studies evaluating the impact of the use of RH-PAT on health outcomes. The report concluded that evidence evaluating the clinical validity of reactive hyperemia peripheral arterial tonometry is insufficient to determine its value in the evaluation of coronary artery disease or to predict cardiovascular adverse events.

van den Heuvel et al. (2017) reported on a study of 93 patients to examine the applicability of PAT to detect a low risk of coronary artery disease (CAD) in a chest pain clinic. PAT was performed resulting in reactive hyperaemia (RHI) and augmentation (Alx) indices. Patients were risk classified according to HeartScore, Diamond and Forrester pretest probability (DF), exercise testing (X-ECG), and computed tomography calcium scoring (CCS) and angiography (CTA). Correlations, risk group differences and prediction of revascularisation within 1 year were calculated. The results indicated that PAT cannot detect a low risk of CAD, possibly because RHI and Alx versus X-ECG, CCS and CTA represent independent processes.

To assess whether endothelial dysfunction, as detected by peripheral artery tonometry, can predict late cardiovascular events, Rubinshtein et al. (2010) induced reactive hyperaemia (RH) following upper arm occlusion of systolic blood pressure in 270 outpatients. The natural logarithmic scaled RH index (L\_RHI) was calculated from the ratio between the digital pulse volume during RH and at baseline. Follow-up was seven years. Seven-year adverse event rate was 48% in patients with L\_RHI < 0.4 vs. 28% in those with L\_RHI ≥ 0.4 (p=0.03). Univariate predictors of adverse events were LRHI, advancing age, and prior coronary bypass surgery. Multivariate analysis identified L\_RHI < 0.4 as an independent predictor of AE (p=0.03). Study limitations include an uncontrolled study design, and dropout rate of 17%.

Hamburg et al. (2008) reported results of a correlational cohort study of Framingham Third generation Cohort participants (n=1957). A fingertip peripheral arterial tonometry (PAT) device was used to measure digital pulse amplitude. Measurements were taken at baseline and in 30 second intervals for four minutes during reactive hyperemia induced by five minute forearm cuff occlusion. The relation of PAT ratio to cardiovascular risk factors was strongest in the 90-120 second postdeflation interval (overall model R<sup>2</sup>=0.159). To determine the relation between the hyperemic response over time following cuff deflation and clinical cardiovascular risk factors, stepwise regression models were performed for the PAT ratio for each 30 second interval with age and sex forced in, selecting from systolic blood pressure, diastolic blood pressure, heart rate, body mass index, total/HDL cholesterol, triglycerides, glucose, diabetes, current smoking, hormone replacement therapy, hypertension treatment, lipid-lowering treatment, and prevalent cardiovascular disease. The relation of PAT ratio to cardiovascular risk factors was strongest in the 90-120 second postdeflation interval (overall model R<sup>2</sup>=0.159). The authors note study findings support further investigations to define clinical utility and predictive value of digital pulse amplitude. The study was limited by uncontrolled design.

#### **Professional Societies/Organizations**

**American College of Cardiology Foundation/American Heart Association (ACCF/AHA):** These organizations published the 2010 Guideline for the Assessment of Cardiovascular Risk in Asymptomatic Adults. The guideline notes that it is unclear whether these measures of peripheral endothelial health provide incremental predictive information when controlling for traditional risk factors. The guideline further notes that due to the limited data available, the writing committee concluded that it was premature to recommend serial FMD measurements to monitor treatment effects. In addition, due to the technical challenges of standardizing measurement of FMD and the relatively modest evidence of incremental change in risk assessment, measurement for risk assessment was not regarded as appropriate for risk assessment in the asymptomatic adult.

**American Society of Echocardiography/Society for Vascular Medicine:** These societies (Roman, et al., 2006) published a report regarding the clinical application of noninvasive vascular ultrasound in cardiovascular risk stratification. The report notes that the ability of flow-mediated endothelium-dependent brachial artery dilation to provide prognostic information in individuals at intermediate- or low-risk, independent of more standard risk-profiling approaches, remains to be identified.

### **Computer-Aided Detection of Chest Radiographs (CPT Codes 0174T, 0175T)**

Computer-aided detection (CAD) systems for computed tomography or digital chest x-rays are software programs that subtract one lung from another to reveal subtle asymmetric opacities, and perform temporal subtraction of prior imaging from the current exam. The basic concept of computer-aided detection (CAD) is to provide computerized image recognition to assist and improve radiologist's interpretation. Through algorithms, CAD technology provides radiologists with regions of interest (ROI) for their interpretation. Although CAD is used most often in mammography, many different types of CAD technologies and/or devices are being developed for detection of various lesions in medical imaging, including conventional x-ray, computed tomography (CT), magnetic resonance imaging (MRI), and ultrasound.

Proponents of computer-aided detection with chest x-ray state that diagnostic accuracy is improved with the use of a CAD program and that CAD can expedite screening of at-risk individuals at an earlier and more curable stage of lung cancer. Potential risks of using CAD with chest x-rays may include the generation of false-positive and false-negative results leading to over- and under-diagnosis. Abnormalities (e.g., scars from smoking, areas of inflammation, or other noncancerous conditions) can mimic lung cancer on x-ray. Subsequent additional testing may cause anxiety for the patient or may lead to unnecessary biopsy or surgery and increase medical costs. Also, the use of CAD programs in screening for lung cancer may detect small tumors that would never become life-threatening, putting a patient at risk for unnecessary treatments for cancer, such as chemotherapy or radiation.

### **U.S. Food and Drug Administration (FDA)**

Deus Technologies received FDA premarket approval for its RapidScreen™ CAD system in July 2001. Its intended use is "to identify and mark regions of interest on digital or digitized frontal chest radiographs. It identifies features associated with solitary pulmonary nodules from 9–30 millimeters (mm) in size, which could represent early-stage lung cancer. The device is intended for use as an aid only after the physician has performed an initial interpretation of the radiograph. The device is of little value when used for patients who are not at high risk for lung cancer."

In 2007, Deus Technologies manufacturer Riverain Medical Group (Miamisburg, OH) received approval for a new trade name. The device, as modified, will be marketed under the trade name OnGuard™ and is indicated "to identify and mark ROIs on frontal chest radiographic films from adult males with an increased risk for lung cancer to bring ROI to the attention of the radiologist after the initial reading has been completed. Thus the system assists the radiologist in minimizing observational oversights by identifying areas on the original chest films that may warrant a second review." In March of 2012, Riverain's OnGuard software was renamed ClearRead Detect™. Currently, Riverain Medical's ClearRead Detect™ CAD System is the only FDA-approved CAD systems with a Product Device Description of "Analyzer, Medical Image" for chest x-rays (Product Code MYN). Other CAD systems (for example, mammography or lung computed tomography) are listed under this same device description.

The FDA approved EDDA Technology's (Princeton Junction, NJ) "IQQA® Chest Software Package" in October 2004 under the Product Device Description of Picture Archiving and Communications System (PACS). It uses a real-time interactive pulmonary nodule analysis system for chest digital radiographic image softcopy reading. Intended use states it is "used during the review of digital chest radiographic images. Combining image viewing, evaluation and reporting tools, the software is designed to support the physician in the identification of lung lesions (e.g. nodules), as well as the confirmation, evaluation and documentation of such physician-identified lesions. The IQQA-Chest software package supports a workflow based on automated segmentation for the visual identification of possible lesions. The tools also allow for regional analysis of possible lesions in terms of size, shape and position, thus aiding the physician in the characterization of physician-identified suspicious lesions." Philips Medical Systems (Hamburg, Germany) has licensed EDDA Technology's IQQA® Chest software and markets it under the name xLNA (x-ray lung node assessment) Enterprise.

### **Literature Review**

There is insufficient evidence in the published, peer-reviewed scientific literature addressing the accuracy and clinical utility of CAD of chest x-rays. Well-designed clinical trials are lacking. Studies are primarily retrospective analyses of registry data and there is concern regarding unacceptable false-positive rates. Retrospective registry studies address multiple variables that may impact accuracy such as the experience and training of radiologist using the CAD program, type of chest x-ray utilized (e.g., temporal subtraction, dual energy subtraction) and region of interest identification parameters in the algorithms themselves (e.g., nodules size, bone suppression, and nodule-in-center or nodule-in-circle criterion). Additionally, screening populations and timing for the use of CAD in the diagnostic work-up vary in studies. The clinical utility of CAD of chest x-rays for lung cancer screening is not established. The FDA wording regarding RapidScreen™ CAD systems notes that the device is of little value when used for patients who are not at high risk for lung cancer (Dellios, et al., (2017); Kligerman, et al., 2013; De Boo, et al., 2011; Meziame, et al., 2012; Szucs-Farkas, et al., 2010; Balkman, et al., 2010; Moore, et al., 2010; White, et al., 2009; Li, et al., 2008; Van Beek, et al., 2008; Bley, et al., 2008; Kakeda, et al., 2004).

### **Professional Societies/Organizations**

**American College of Radiology (ACR):** ACR (Mohammed, et al., 2013) published appropriateness criteria for the screening of pulmonary metastases. According to the ACR, computer-aided detection (CAD) for pulmonary metastatic disease has been adapted to chest CT. Although these programs are in their developmental phases, the ACR notes it has been suggested that CAD can be used as a second look after the radiologist has completed reviewing the study. However, the ACR notes these applications require more development and can only be used when there is limited breathing artifact and stable lung expansion. CAD is still in the investigative phase and has limited use in evaluating patients with pulmonary metastatic disease.

### **Intermittant and Continuous Measurement of Wheeze Rate for Bronchodilator or Bronchial Challenge (CPT code 94799)**

The American Thoracic Society Committee on Pulmonary Nomenclature defines wheezing as high-pitched (dominant frequency of  $\geq 400$  Hz) continuous adventitial lung sounds (i.e.,  $>250$ msec) (Schraufnagel and Murray, 2010). The sound is generated by turbulence in larger airways that collapse with forced expiration (Boat and Green, 2011). Repeated examination may be required to verify a history of wheezing and should be directed toward assessing air movement, ventilatory adequacy, and evidence of chronic lung disease (Boat and Green, 2011). Computerized lung sound analysis involves recording the patient's lung sounds via an electronic device, followed by computer analysis and classification of lung sounds based on specific signal characteristics. Intermittant measurement of wheeze rate by pulmonary sound analysis has been proposed for use in bronchodilator or bronchial challenge diagnostic evaluation. Continuous measurement of wheeze rate by sound analysis has been proposed during treatment assessment such as bronchodilator or bronchial challenge evaluations, and during sleep for documentation of nocturnal wheeze and cough.

### **U.S. Food and Drug Administration (FDA)**

Several devices have received FDA approval for the measurement of wheeze rate. The PulmoTrack™ 2020 System (iSonea, formerly KarmelSoniz, Binyamina, IS, US office: Alta Loma, CA) received 510(k) approval in March 2011. The approval summary notes "The PulmoTrack™ 2020 is intended for the analysis, interpretation and documentation of lung sounds. The PulmoTrack™ 2020 is indicated for use by or under the supervision of a physician while carrying out a provocation test, administering a bronchodilator or performing a physical examination in pulmonary function testing environment when there is a need for performing an acoustic pulmonary function measurement that quantifies the presence of wheezing. It is also indicated when there is a need to listen to amplified and filtered breath sounds. The PulmoTrack™ 2020 is indicated for patient population above two years old." The WIM-PC received 510(k) approval in November 2007. The FDA summary notes "The WIM-PC is intended for the analysis, interpretation and documentation of lung sounds."

### **Literature Review**

Randomized controlled clinical trial data in the published peer-reviewed scientific literature are scarce to inform the effectiveness and clinical utility of wheeze rate measurement. Gurung et al. (2011) performed a systematic review and meta-analysis to estimate the sensitivity and specificity of computerized lung sound analysis for the detection of lung sounds. Eight studies were selected for review. Overall sensitivity for the detection of wheezes or crackles was 88%, and specificity was 85%. The authors noted there is a lack of standardization across studies in the methods used for lung sound recording, computer algorithms for signal analysis and statistical methods for outcome analysis. Further research is needed to address the effectiveness of specific combinations of electronic devices and computing algorithms in clinical and community settings.

Beck et al. (2007) evaluated the use of computerized quantification of wheezing and crackles compared to a clinical score in assessing the effect of inhaled albuterol or inhaled epinephrine in infants with RSV bronchiolitis

during a double blind, randomized, controlled nebulized treatment pilot study. Computerized quantification of wheezing and crackles (PulmoTrack) and a clinical score were performed prior to, 10 minutes post and 30 minutes post treatment. Breath segments containing at least five consecutive interference-free breaths were analyzed for a total of 20 breaths. Wheeze Rate (percent of time wheezing of total breath time) and crackle count (number of crackles per breath) were determined by the PulmoTrack® for each breath cycle, and averaged over the 20 breaths. Satisfactory lung sounds recording and analysis was achieved in all subjects. There was no significant change in objective quantification of wheezes and crackles or in the total clinical scores either within the groups or between the groups. Although data suggest that automated wheeze rate measurement is feasible, the authors note that a larger study is necessary to assess the correlation between the computerized crackle and wheeze counts and the Clinical Score in response to treatment in RSV bronchiolitis.

#### **Cryoablation of Lung Tumors (CPT Code 0340T, 32994) (Code 0340T deleted 12/31/2017; use 32994 to report)**

Pulmonary tumor cryoablation involves the destruction of tumor tissue using extreme cold. This is also known as cryoablation, cryosurgery, or cryotherapy. In this procedure a small thin wand-like needle, known as a cryoprobe, is inserted through the skin of the chest and between the ribs. Under computerized tomography (CT) guidance, the probe is advanced into the lesion of the lung and any tumor extensions to the pleura and/or chest wall. Compressed argon gas is passed through the probe and into the tumor, which freezes it and destroys the tissue. Treatment with the probe usually takes several minutes and may include repositioning the probe within the lesion so that overlapping ablations treat the entire tumor.

#### **Literature Review**

Randomized controlled clinical trial data are lacking in the published peer-reviewed scientific literature to demonstrate the safety and effectiveness of pulmonary tumor ablation by cryoablation. Studies are limited by uncontrolled design and small patient populations. Additional well-designed high quality studies are necessary to inform on health outcomes. Further, published professional consensus is necessary before this treatment can be translated into routine clinical practice.

Moore et al. (2015) reported on a retrospective study that evaluated long-term survival in 45 patients with early stage non-small cell lung cancer (NSCLC) treated with cryoablation treatment. The study findings included five year survival rate 67.8% ± 15.3; the cancer-specific survival rate was 56.6% ± 16.5; and the 5-year progression-free survival rate was 87.9% ± 9. The combined local and regional recurrence rate was 36.2%. Major

complications occurred 6.4% of patients that included two cases of hemoptysis and a prolonged placement of a chest tube requiring mechanical sclerosis in one patient. There were no deaths in the first 30 days after treatment.

Hayes published a technology directory report regarding cryoablation for treatment of non-small cell lung cancer (NSCLC) (Hayes, 2015; 2017). The review included one randomized controlled trial (RCT), six nonrandomized comparative studies, and one uncontrolled study, with sample size of 36 to 346 patients. The body of evidence concerning cryoablation for NSCLC is moderate in size and low in overall quality. Results of the available studies provide preliminary evidence that cryoablation is a reasonably safe and effective treatment for NSCLC. While the results of some of the studies were somewhat conflicting or inconclusive, there is some evidence of improved survival when cryoablation is used alone or with other therapies. Additional well-designed studies with long-term follow-up are needed to define the clinical role of cryoablation relative to other common therapies for NSCLC such as surgery, RFA, chemotherapy, radiation therapy, and immunotherapy.

Yashiro et al. (2013) reported results of a prospective study of 71 consecutive patients with 210 pulmonary tumors treated with 102 sessions of percutaneous cryoablation of lung tumors. A mean of 1.4 sessions was performed per case. A maximum of four cryoprobes was used on one lesion; the number and diameter of the probes were based on estimated tumor size. Every procedure was performed using a triple freeze/thaw protocol. High-pressure argon gas was used for freezing. There was no procedural mortality. Of 210 tumors, technical success was achieved for 167 (79.5%). At a median follow-up of 454 days, local progression occurred in 50 tumors (23.8%). One-, 2-, and 3-year local progression-free rates were 80.4%, 69.0%, and 67.7%, respectively, and technique effectiveness rates were 91.4%, 83.0%, and 83.0%, respectively. Existence of a thick vessel (diameter  $\geq 3$  mm) no more than 3 mm from the edge of the tumor was assessed as an independent factor (HR, 3.84; 95% CI, 1.59–9.30;  $P = .003$ ) associated with local progression by multivariate analysis. Although results are promising, study limitations include uncontrolled design, and small patient numbers.

Kawamura et al. (2006) conducted a nonrandomized uncontrolled study to evaluate cryoablation of 35 pulmonary metastatic tumors in 20 patients who were not surgical candidates. In all cases cryoablation was performed percutaneously under CT guidance with local anesthesia. A total of 22 sessions of cryoablation were performed. Pneumothorax occurred in 11 of the 22 sessions, primarily after the completion of the ablation procedure. A chest tube was inserted in one case, transient needle aspiration was performed in three cases, and in seven cases no additional treatment was given. Phrenic nerve palsy occurred during one session. Mean hospital stay after treatment was 2.6 days, although for the initial five sessions, it was 5.4 days. There were no treatment-related deaths or conversion to surgical intervention. The follow-up period was 9 to 28 months. Local recurrence occurred in 7 (20%) of tumors. Five patients underwent repeat cryoablation without complications. Study limitations which preclude the ability to apply results to other populations include uncontrolled randomized design and small study populations.

### Professional Societies/Organizations

**National Comprehensive Cancer Network™ (NCCN™):** The NCCN (2017) guidelines do not contain detailed information on cryoablation for NSCLC. Cryotherapy is briefly mentioned as follows (NCCN, 2017):

- Resection is the preferred local treatment modality (other modalities include radiotherapy ablation, cryotherapy, and stereotactic ablative radiotherapy).

### Use Outside of the US

**European Society for Medical Oncology (ESMO):** ESMO published clinical practice guidelines for metastatic non-small cell lung cancer (Novello, et al., 2016). The guidelines note that in case of symptomatic major airways obstruction or postobstructive infection, endoscopy debulking by laser, cryotherapy or stent placement may be helpful (III, C).

Levels of evidence and grades of recommendation

III Prospective cohort studies

C Insufficient evidence for efficacy or benefit does not outweigh the risk or the disadvantages (adverse events, costs), optional

### **Fecal Calprotectin Testing (FC) (CPT Code 83993)**

This laboratory test measures the level of calprotectin in stool. Calprotectin is a calcium and zinc binding protein that is found predominantly in neutrophils. The concentration of calprotectin is higher in feces compared to plasma and can be measured by enzyme-linked immunosorbent assay (ELISA) using less than five grams of stool. Although the normal range has been defined for FC, an optimal cutoff point for distinguishing inflammatory bowel disease (IBD) from other diagnoses has not been defined (von Roon et al. 2007). It has been studied as a surrogate marker of intestinal inflammation in inflammatory bowel diseases (e.g., Crohn's disease, ulcerative colitis), colorectal cancer, diverticular disease, and polyposis of the colon. It has also been studied as a marker to predict response to treatment and relapse of disease.

### **U.S. Food and Drug Administration (FDA)**

PhiCal™ Fecal Calprotectin Immunoassay (Genova Diagnostics, Inc., Ashville, NC) received Class II device approval in 2006. The immunoassay is a lab test that measures the amount of fecal calprotectin in a patient's stool sample. The PhiCal test is indicated for use as an in vitro diagnostic to aid in the diagnosis of inflammatory bowel diseases (IBD) (Crohn's disease and ulcerative colitis), and to differentiate IBD from irritable bowel syndrome (IBS) when used in conjunction with other diagnostic testing and the total clinical picture.

### **Literature Review**

Randomized controlled clinical trial data are lacking regarding the clinical utility of fecal calprotectin testing to inform diagnosis, or predict relapse or response to treatment for IBD or any indication. Although patient numbers included in published studies are large, a number of study limitations have been identified by authors including uncontrolled and heterogeneous study design, and heterogeneous patient populations. Further, in some studies it is unknown whether FC samples were obtained before commencing treatment, which may be a major confounder in reports of diagnostic accuracy (Henderson, et al., 2013). In the study by Henderson (2013) the authors note "The assessment of methodological quality determined that there were deficiencies in all the studies evaluated, but especially with regard to important aspects, such as the use of a representative spectrum of patients, an acceptable reference standard (upper and lower endoscopy), and the poor reporting of current treatment modalities in use during FC sampling."

**Inflammatory Bowel Disease (IBD):** El-Matary et al. (2017) reported on a retrospective cohort study that examined the impact of fecal calprotectin (FCal) measurements on decision-making and clinical care of children with IBD. FCal, clinical activity indices, and blood markers were measured in 77 (115 fecal samples) children with diagnoses of IBD. Pearson correlation coefficient analysis was performed to examine association between FCal and other markers. Then decisions based on FCal measurements were prospectively documented and participants were evaluated three to six months later. FCal positively correlated with clinical activity indices ( $r = 0.481$ ,  $P < 0.05$ ) and erythrocyte sedimentation rate ( $r = 0.40$ ,  $P < 0.05$ ) and negatively correlated with hemoglobin ( $r = -0.40$ ,  $P < 0.05$ ). Sixty-four out of 74 (86%) positive FCal measurements ( $\geq 250$   $\mu\text{g/g}$  of stools) resulted in treatment escalation with subsequent significant clinical improvement while in the FCal negative group, 34 out of 41 (83%) measurements resulted in no change in treatment and were associated with remission on follow-up. The study was limited by lack of randomization, retrospective design, and small sample size in particular for those for those who had colonoscopy.

Abej et al. (2016) reported on a prospective cohort study performed to determine the relationship between fecal calprotectin (FCAL) and imaging studies and other biochemical inflammatory markers and the impact of FCAL measurements on decision-making in IBD patient management in usual clinical practice. The study included 240 persons with IBD. The correlation between FCAL values and other markers for disease activity such as serum albumin (alb), hemoglobin (Hg), and C-reactive protein (CRP) and diagnostic imaging or colonoscopy were examined. FCAL  $\geq 250$  mcg/g of stool was considered a positive result indicating active IBD. The results of 183 stool samples (76.3%) were returned. The return rate in the pediatric and adult cohorts was 91% ( $n = 82$ ) and 67.3% ( $n = 101$ ), respectively ( $P < 0.0001$ ). Positive FCAL was associated with colonoscopy findings of active IBD ( $P < 0.05$ ), low albumin ( $P < 0.05$ ), anemia ( $P < 0.01$ ), and elevated CRP ( $P < 0.01$ ). There was no significant difference for FCAL results by outcomes on small bowel evaluation among the 21 persons with small bowel CD.

Most persons (87.5%) with normal FCAL and no change in therapy remained in remission during subsequent 3 months. Of 11 subjects with a positive FCAL who underwent imaging, only 6 had active disease on imaging; a positive FCAL was not significantly associated with radiologic evidence of active disease ( $P = 0.31$ ). This study was limited by lack of controls, and the small number who underwent imaging and endoscopy.

Bar-Gil Shitrit et al. (2016) reported on a study that prospectively assessed the value of fecal calprotectin and lactoferrin in 68 patients with Crohn's disease (CD) to predict capsule endoscopy (CE) findings. Stool samples for calprotectin and lactoferrin and blood samples were collected for relevant parameters. Correlation between fecal markers and CE findings was assessed and receiver operating characteristic (ROC) curves were built to determine the predictive values of fecal markers for the diagnosis of CD. Fecal calprotectin data was available for all the patients and lactoferrin data for 38. CE findings compatible with CD were found in 23 (33%) patients and 45 (67%) were negative for CD. The average age of the CD group was 34 compared to 46 in the non-CD group ( $p = .048$ ). Median calprotectin and lactoferrin in the CD group and in the control group were 169 mg/kg vs. 40 ( $p = .004$ ) and 6.6 mg/kg versus 1 ( $p = .051$ ), respectively. The area under the ROC curve was 0.767 for calprotectin and 0.70 for lactoferrin. A fecal calprotectin concentration of 95 mg/kg and fecal lactoferrin of 1.05 mg/kg had a sensitivity, specificity, positive predictive value and negative predictive value of 77 and 73%, 60 and 65%, 50 and 50%, and 84 and 84% in predicting CE findings compatible with CD. The study is limited by small number of participants and lack of controls.

Several meta-analyses of prospective and registry data have been performed to examine the predictive capacity of fecal calprotectin in individuals with IBD (e.g., Crohn's disease, ulcerative colitis). Reported results have been inconsistent with a wide variation in sensitivity and specificity of FC for included studies, ranging from 61-100% and 71-100%, respectively for diagnosis of IBD and other intestinal disorders. Sensitivity and specificity to predict relapse are 43-80% and 48-73%, respectively (Heida, et al., 2017; Henderson, et al., 2013; Kostakis, et al., 2012; Mao, et al., 2012; Jellema, et al., 2011; Laharie, et al., 2011; van Rheenen, et al., 2010; von Roon, et al., 2007).

In several studies (Hukkinen, et al., 2016; Henderson, et al., 2013; van Rheenen, et al., 2010), results regarding specificity of FC testing in children were significantly different compared with those for adults (96% and 68-97%, respectively). In addition, recent studies and meta-analysis have been published regarding the use of fecal calprotectin in management of IBD (Bressler, et al., 2015; Wright, et al., 2015; Kennedy, et al., 2015; Mosli, et al., 2015; Menees et al., 2015; Lin, et al., 2014; Sandborn, et al., 2016; Chey, et al., 2015). These studies examine the accuracy of the test, but do not indicate the clinical utility of fecal calprotectin in the management of IBD. The tests did not substantiate the use of this test in altering the management of the condition, or reducing or eliminating other testing for the condition.

Hayes published a directory report for fecal calprotectin (FC) assay for monitoring postoperative recurrence (PER) of Crohn Disease (CD) (2013, 2017). It was found that overall quality of the body of evidence pertaining to the use of FC testing systems for the evaluation of postoperative endoscopic recurrence (PER) in patients with CD was considered to be low with one study rated as good quality; five as fair quality; and, five as poor quality. The major individual study limitations included small sample sizes; study design; lack of blinding; no follow-up; unclear, extended, or varying lengths time between FC stool sample collection and colonoscopy; lack of correction for multiplicity in analysis; multiple endoscopic procedures per patient unaccounted for in the analysis; and nonuniform postoperative treatment. The study concluded that the available evidence indicates that FC testing generally has high negative predictive value (NPVs) and moderate sensitivity but low-to-moderate specificity and positive predictive value (PPVs) for the prediction of PER in patients with CD. With a high NPV, patients and clinicians can have a high assurance that a negative result on an FC test suggests that PER will not occur, thus potentially avoiding or delaying invasive endoscopic procedures. The study noted that however, NPVs and sensitivity values varied across some studies; thus, additional research is needed to define uniform and optimal cutoffs for FC testing to predict and monitor PER of CD. In addition, no direct evidence was available regarding the clinical utility of FC testing to change management or improve outcomes in patients with CD following ileocolic resection. Additional good-quality, blinded studies of sufficient size, design, and duration are required to evaluate the clinical utility of FC testing for monitoring PER of CD.

Hayes published a directory report for the use of fecal calprotectin (FC) assay for monitoring disease activity in Crohn disease (CD) (Hayes, 2013; 2017). The review found that in general, FC testing provides moderate-to-

high sensitivity, specificity, PPV, NPV, and diagnostic accuracy for the prediction of disease activity using endoscopic or clinical indices in patients with CD and that no studies directly addressed measures of clinical utility. The conclusions of the report included that:

- The available evidence suggests that FC testing is safe and may have promise for monitoring disease activity due to the moderate-to-high diagnostic sensitivity and accuracy of this test to predict disease activity in patients with CD. However, no direct evidence was available regarding the clinical utility (i.e., change in patient management or improved clinical outcomes) of FC testing for monitoring disease activity in patients with CD. In addition, the specificity, positive predictive value (PPVs), and negative predictive value (NPVs) varied across studies, and additional studies are required to define uniform cutoffs for FC testing to predict and monitor CD activity.
- Across 12 studies assessing FC testing for the prediction of endoscopic disease activity, sensitivity ranged from 70% to 94.1% and specificity ranged from 40% to 97%. PPV and NPV ranged from 48.5% to 98% and 40% to 96.6%, respectively. Four studies reported diagnostic accuracy, which ranged from 71% to 87%.
- In three studies, FC testing had 50% to 80% sensitivity and 74.4% to 88% specificity for monitoring changes in clinical disease activity. PPV and NPV ranged from 27.6% to 76% and 71% to 96.8%, respectively.
- In one study, FC testing had a moderately high specificity (82%), moderate NPV (75%), and very low sensitivity (37%) for detection of clinical loss of response (LOR) to infliximab in patients undergoing maintenance therapy.
- There do not appear to be any safety concerns with the use of FC testing to predict and monitor CD activity, although the potential risk for false-positive results could result in unnecessary endoscopic procedures.
- Additional good-quality, blinded studies of sufficient size, design, and duration in well characterized patient populations are required to evaluate the clinical utility of FC testing for monitoring disease activity in patients with CD.

Although several clinical trials reflect abnormal or elevated FC levels in individuals with inflammatory bowel disease compared with controls, the clinical utility of fecal calprotectin testing to impact management and improve overall health outcomes has not been demonstrated. Large randomized controlled trials are necessary to establish the role of FC testing when compared to available diagnostic tests.

**Colorectal Cancer:** Similar to IBD, RCT data are lacking in the published, peer-reviewed scientific literature to evaluate the clinical utility of FC testing for screening and diagnosis of colorectal cancer (CRC) in adults and children. Although levels of fecal calprotectin may be elevated in individuals with CRC compared with healthy control subjects, several meta-analyses of prospective and retrospective studies reflect inconsistent sensitivity and specificity with values of 36-75% and 64-84% respectively (von Roon, et al., 2007; Shitrit, et al., 2007). The role of FC testing as a means to diagnose CRC has not been established.

**Other Intestinal Conditions:** FC testing has also been proposed for other conditions such as irritable bowel syndrome, colonic polyposis, diverticular disease, and diarrhea (Tursi, et al., 2014; Licata, et al., 2012; Pezzilli, et al., 2008; Parsons, et al., 2014). Randomized controlled trial data are lacking in the published peer-reviewed scientific literature demonstrating the ability to impact care management or improve patient health outcomes with FC testing. Further, there is a lack of published literature reflecting that this is considered a standard of care option for these indications. At this time there is insufficient evidence to determine the role and clinical utility of such testing.

### Professional Societies

**American College of Gastroenterology (ACG):** ACG published updated guidelines for management of Crohn's Disease in adults (Lichtenstein, et al., 2018). The guidelines include the following recommendation:

- Diagnosis: Fecal calprotectin is a helpful test that should be considered to help differentiate the presence of IBD from irritable bowel syndrome (IBS) (strong recommendation, moderate level of evidence).
- In patients who have symptoms of active Crohn's disease, stool testing should be performed to include fecal pathogens, *Clostridium difficile* testing, and may include studies that identify gut inflammation such

as a fecal calprotectin and may include studies that identify gut inflammation such as a fecal calprotectin.(summary statement , no level of evidence)

- Fecal calprotectin and fecal lactoferrin measurements may have an adjunctive role in monitoring disease activity. .(summary statement , no level of evidence)

Level of evidence:

Moderate: (further research would be likely to have an impact on the confidence in the estimate of effect)

Recommendation grading:

Strength of a recommendation graded as “strong” when the desirable effects of an intervention clearly outweigh the undesirable effects.

Summary statements are descriptive and do not have associated evidence-based ratings.

**American Gastroenterological Association (AGA):** the AGA published a clinical care pathway for Crohn’s disease. In the section for assessing inflammatory status, fecal calprotectin is listed along with other lab testing that includes CBC, CRP, CMP, and ESR. There is no evidence level included in the clinical care pathway.

#### Use Outside of the US

**European Society of Pediatric Gastroenterology, Hepatology, and Nutrition (ESPGHAN)/North American Society of Pediatric Gastroenterology, Hepatology, and Nutrition (NASPGHAN):** In joint recommendations From these organizations fecal calprotectin (FC) and fecal leukocytes (FL) are described as markers of bowel inflammation that have been shown to correlate with clinical measures of disease activity in patients who have Crohn’s disease. They note that they may help clinicians ascertain the nature and severity of disease, in particular if prior measurements are available for comparison. Although FC and FL have also been shown to have potential to predict relapse, there is insufficient evidence to recommend routine use of these markers for surveillance of Crohn’s disease (Rufo et al., 2012).

**National Institute for Health and Care Excellence (NICE):** NICE published guidance for fecal calprotectin diagnostic tests for inflammatory diseases of the bowel (2013; 2017). Recommendations include:

- Fecal calprotectin testing is recommended as an option to support clinicians with the differential diagnosis of inflammatory bowel disease (IBD) or irritable bowel syndrome (IBS) in adults with recent onset lower gastrointestinal symptoms for whom specialist assessment is being considered, if:
  - Cancer is not suspected, having considered the risk factors (for example, age) described in the NICE guideline on suspected cancer
  - Appropriate quality assurance processes and locally agreed care pathways are in place for the testing.
- Fecal calprotectin testing is recommended as an option to support clinicians with the differential diagnosis of IBD or non-IBD (including IBS) in children with suspected IBD who have been referred for specialist assessment, if:
  - Appropriate quality assurance processes and locally agreed care pathways are in place for the testing.

**World Gastroenterology Organisation (2015):** The global guideline for irritable bowel syndrome (IBS), lists fecal inflammation marker (e.g., calprotectin) in the IBS Level I diagnostic cascade.

**Transanal Radiofrequency Therapy for Fecal Incontinence (e.g., SECCA Procedure) (CPT Code 46999)**

Fecal incontinence is the inability to control the passage of gas, liquid and/or solid feces due to the loss of the coordinated function of the muscles and/or nerves of the rectum, anal canal, and pelvic floor. Treatment of minor incontinence (i.e., incontinence to flatus and occasional seepage of liquid stool) may be controlled by changes in diet and dietary habits, medication (e.g., bulking agents, antidiarrheal drugs), and bowel training (e.g., Kegel exercises, biofeedback). In the case of major incontinence (i.e., frequent loss of solid waste material) or incontinence unresponsive to conservative measures, surgical intervention may be indicated. In the event of an isolated sphincter defect, the standard surgical treatment is sphincteroplasty. Other surgical procedures include repair of rectocele or rectal prolapse and, in severe cases, fecal diversion (i.e., colostomy) (Kim, et al., 2009; Lefebure, et al., 2008; Rao, 2004; Wexner and Sands, 2003; Takahashi, et al., 2002).

Transanal radiofrequency therapy (e.g., Secca® procedure) is a proposed alternative therapy for the treatment of fecal incontinence for patients who have not responded to medical therapy and are not good surgical candidates or have failed surgical intervention. The Secca procedure is noninvasive, typically takes 30–45 minutes, and is performed in an outpatient setting under local anesthesia and sedation. It is also proposed that there are fewer complications following the Secca procedure compared to invasive surgical procedures.

Radiofrequency therapy is based on the theory that “collagen deposition and subsequent scarring may increase one’s ability to recognize and retain stool and permit improved continence” (Parisien and Corman, 2005). An anoscopic device uses four electrodes to deliver controlled radiofrequency energy to the sphincter muscles surrounding the anal canal. The energy creates precise, submucosal burn lesions, triggering collagen contraction. The lesions are subsequently resorbed, remodeling the tissue. The remodeling is proposed to improve barrier function of the anal sphincter (Efron, et al., 2003; Takahashi, et al., 2002).

#### **U.S. Food and Drug Administration (FDA)**

The Secca® System (Curon Medical Inc., Sunnyvale, CA) was approved by the FDA as a 510(k) Class II device for general use for electrosurgical coagulation and “for use specifically in the treatment of fecal incontinence in those patients with incontinence to solid or liquid stool at least once per week and who have failed more conservative treatment” (FDA, 2002).

#### **Literature Review**

The Agency for Healthcare Research and Quality (AHRQ) published a comparative effectiveness review for treatments for fecal incontinence (Forte, et al., 2016). The review found only case series studies for SECCA procedure, no randomized controlled trials or observational studies were found. It was found that evidence was insufficient regarding this procedure.

There is insufficient evidence in the published peer-reviewed scientific literature to support the effectiveness of transanal radiofrequency therapy (e.g., Secca procedure) for the treatment of fecal incontinence. Studies are primarily in the form of prospective case series with small patient populations (n=8–50). With the exception of one, five-year study (Takahashi-Monroy, et al., 2008) follow-ups were short-term, ranging from 6–12 months. Various questionnaires (e.g., Fecal Incontinence Severity Index, Fecal Incontinence-related Quality of Life questionnaire, Vaizey scale) were utilized to measure quality of life (e.g., coping, depression, embarrassment) outcomes and results were inconsistent. Typically there were no significant improvements in physical component outcomes, such as anorectal manometry parameters, pudendal nerve motor latency, endoanal ultrasound results, and the thickness of internal anal sphincters. Some studies reported numerous complications while others reported no complications (Ruiz, et al., 2010; Kim, et al., 2009; Lefebure, et al., 2008; Takahashi-Monroy, et al., 2008; Felt-Bersma, et al., 2007; Efron, et al., 2003; Takahashi, et al., 2003). Studies comparing the use of transanal radiofrequency therapy to established medical and surgical treatment options are lacking.

#### **Professional Societies/Organizations**

**American College of Gastroenterology (ACG):** in the ACG clinical guideline for management of benign anorectal disorders (Wald, et al., 2014) for the treatment of fecal incontinence it is noted regarding the Secca procedure, that there is insufficient evidence to recommend radiofrequency ablation treatment to the anal sphincter (SECCA) at this time (no recommendation, insufficient evidence).

**American Society of Colon and Rectal Surgeons:** In their practice parameters for the treatment of fecal incontinence, the American Society of Colon and Rectal Surgeons (Tjandra, et al., 2007) discussed the medical (e.g., fiber intake, antidiarrheal agents, enemas, laxatives, suppositories, anal plug) and surgical (e.g., sphincter repair, injectable therapy, sacral nerve stimulation, dynamic graciloplasty, artificial bowel sphincter, stoma) treatment options for this condition. Based on studies by Takahashi et al. (2003) (n=10) and Efron et al. (2003) (n=50), the ASCRS stated that the Secca procedure may be useful for selected patients with moderate fecal incontinence.

#### **Use Outside of the US**

**National Institute for Health and Care Excellence (NICE):** In an interventional procedure guidance document, NICE (2011) (United Kingdom) stated that endoscopic radiofrequency therapy of the anal sphincter for the treatment of fecal incontinence raised no major safety concerns, but the procedure should only be carried out in units specializing in the assessment and treatment of fecal incontinence. NICE noted that further research is needed to clearly define the appropriate patient group for this procedure. The guidance was based on three case series with small patient populations (n=19–50).

**Endoscopic retrograde cholangiopancreatography (ERCP), with optical endomicroscopy (CPT code 0397T)**

Optical microscopy, also known as confocal laser endomicroscopy (CLE), is an emerging endoscopic technology that permits high-resolution assessment of gastrointestinal mucosal histology at a cellular and sub-cellular level. CLE and endocytoscopy can be performed with probe-based systems that are passed through the working channel of an endoscope. A confocal miniprobe is a flexible probe-based system (Cellvizio, Mauna Kea Technologies, Paris, France) that is used as an alternative to a confocal laser endomicroscope. In probe-based confocal laser endomicroscopy (pCLE), both the laser scanning unit and light source are outside the body of the patient, which makes the confocal miniprobe a "passive" conduit. The miniprobes are very flexible and can be passed through the working channel of a standard endoscope. The indications for confocal laser endomicroscopy (CLE) are still being defined. In general, the technology is used to target biopsies of abnormal tissue and to avoid taking biopsies of normal tissue. A use of this technology that is being investigated is the differentiation of benign from malignant biliary strictures with probe-based CLE (Meining, [UpToDate], 2017).

**U.S. Food and Drug Administration (FDA)**

In 2012 the Cellvizio® 100 Series System and Cellvizio® System with Confocal Miniprobes received 510(k) premarket approval for the GastroFlex M" series of Confocal Miniprobes" which are intended to allow imaging of the internal microstructure of tissues in the upper gastrointestinal tract including biliary and pancreatic ducts, accessed by an endoscope or endoscopic accessories. The Cellvizio 100 Series is a confocal laser imaging system with a variety of fiber optic probes that is intended to allow confocal laser imaging of the internal microstructure of tissues in anatomical tracts, i.e. gastrointestinal or respiratory, accessed through an endoscope.

**Literature Review**

Fugazza et al. (2016) systematic review is to analyze the current literature on confocal laser endomicroscopy (CLE) and to evaluate the applicability and diagnostic yield of CLE in patients with gastrointestinal and pancreatobiliary diseases. The review included 102 prospective and retrospective clinical studies that evaluated the sensitivity, specificity, or accuracy of CLE. Regarding the use of CLE in biliary duct, it was found that the addition of CLE to histological examination results in a significant increase in diagnostic reliability. Currently, biliary strictures are staged using a combination of endoscopic ultrasound and advanced imaging techniques, such as computed tomography (CT), magnetic resonance imaging (MRI), or EUS, with endoscopic retrograde cholangiopancreatography (ERCP) typically used for tissue sampling, including biopsy and cytological brushing. The current sensitivity of each of these methods is quite low, ranging from 20% to 60%. The present meta-analysis demonstrated that combining CLE with ERCP yields high sensitivity (90%) in the assessment of biliary strictures. The authors conclude that although CLE has several promising applications, its use has been limited by low availability, high cost, and the necessity of specific operator training. The review noted that In order to implement CLE in routine clinical practice there is a need for further clinical trials with a particular focus on cost-effectiveness and medicoeconomic analyses, as well as standardized institutional training.

Meining et al. (2011) reported on a prospective observational multicenter study of 102 patients with indeterminate pancreaticobiliary strictures. Clinical information, ERCP findings, tissue sampling results, and pCLE videos were collected prospectively. A presumptive diagnosis was provided based on probe-based confocal laser endomicroscopy (pCLE) during the procedure before pathology results were available. Patients received at least 30 days of follow-up until definitive diagnosis of malignancy was established or one-year follow-up if index tissue sampling was benign. The main outcome measurements were diagnostic accuracy, sensitivity, specificity of ERCP-guided pCLE compared with ERCP with tissue acquisition. Eighty-nine patients were able to be evaluated with CLE, with 40 patients were proven to have cancer. CLE had a sensitivity of 98% and a specificity of 67% for diagnosing malignancy.

**Professional Societies/Organizations**

**American Society for Gastrointestinal Endoscopy (ASGE):** the ASGE published a technology evaluation status report on confocal laser endomicroscopy (ASGE, 2014). The report notes that on probe-based confocal

laser endomicroscopy (pCLE) allows in vivo real-time visualization of biliary strictures via a dedicated probe passed through a cholangioscope or catheter for ERCP. pCLE can provide real-time microscopic images of the biliary epithelium, thereby providing histological information that is not otherwise available during ERCP.

The report identified several issues pertaining to CLE that deserve further investigation:

- Further studies evaluating the applicability and practicality of CLE, especially in community settings are needed. Although it appears that the current studies of CLE seem promising, these have primarily been in academic centers and their generalizability in nonacademic practices is unknown.
- Additional studies evaluating the learning curve of CLE image interpretation, use of CLE devices, and additional time needed to perform the procedure are needed.
- The clinical efficacy of the technology and its cost-effectiveness compared with other available advanced imaging technologies needs further study.
- Improvements in CLE imaging and image interpretation are needed. Combining CLE imaging with newer molecular markers and the development of computer-based algorithms may be possible avenues for further research in this area.

The report concluded that CLE is an emerging technology that in the bile duct and within pancreatic cysts, it can provide surrogate real-time histological information that has previously been unavailable. The limitations of CLE include the high cost of the equipment and probes, the lack of proven efficacy compared with other widely available advanced imaging techniques, and the need for either intravenous or topical fluorescent contrast agents. The report notes that before the technology can be widely accepted, many further studies are needed to determine its clinical efficacy and evaluate its cost-effectiveness and its utilization in both academic and community settings.

#### **Wireless Gastrointestinal Motility Monitoring System (SmartPill®) (CPT Code 91112)**

The SmartPill Gastrointestinal (GI) Monitoring System® (The SmartPill Corporation, Buffalo, NY) has been proposed as an alternative testing method for the diagnosis of gastric conditions and intestinal motility disorders such as gastroparesis and chronic constipation. The system records pH and pressure measurements from the entire length of the gastrointestinal tract for use by physicians to aid in the evaluation of gastrointestinal motility diseases and conditions. Sensors on board an ingestible capsule measure pH and pressure as the capsule travels the length of the GI tract. Measurements are transmitted from the capsule within the GI tract via radiofrequency signal to a patient worn receiver and subsequently downloaded for analysis and review. Next, software performs data analyses providing the physician with a printable report containing regional gut transit times: gastric emptying or transit time (GET), small bowel transit time (SBTT), combined small and large bowel transit time (SLBTT), colonic transit time (CTT) and whole gut transit time (WGTT). The capsule is expelled naturally from the body.

#### **U.S. Food and Drug Administration (FDA)**

The SmartPill GI Monitoring System® was approved in 2006 by the U.S. by the Food and Drug Administration (FDA) under the 510(k) process. Indications for use state SmartPill is used in evaluating patients with suspected gastroparesis. In October 2009, the SmartPill was FDA-approved for the evaluation of colonic transit in patients with chronic constipation, to aid in differentiating slow and normal transit constipation. It is not indicated for use in children.

### **Literature Review**

Hayes (2017) published a directory report for wireless capsule systems for diagnosis of gastroparesis and monitoring of gastrointestinal motility. The review included 13 studies of wireless capsule systems for detection of GI motility disorders that were reported in 14 publications with three cross-sectional comparative studies, seven prospective case-control studies, and three retrospective pretest/posttest studies. Wireless motility capsule (ten studies) or wireless capsule endoscopy (three studies) were compared to reference standards (i.e., gastric scintigraphy, small bowel barium transit, and radiopaque markers). The findings of the report note that although 13 studies were identified that compared wireless capsule systems with other methods for detection of GI motility disorders, these studies provide limited evidence concerning the accuracy of the wireless capsule systems and no reliable evidence that use of these systems improves patient outcomes.

The Agency for Healthcare Research and Quality (AHRQ) published a comparative effectiveness review for wireless motility capsule (WMC) versus other diagnostic technologies for evaluating gastroparesis and constipation (Stein, et al., 2013). The review noted WMC appears to be accurate in detection of gastroparesis and slow-transit constipation and may provide increased diagnostic gain as compared with standard motility testing. While the strength of evidence (SOE) is low, the data were relatively consistent and suggested that this modality is no less sensitive than conventional testing. The review noted that the evidence is insufficient to determine whether use of WMC will improve outcomes of care.

Published studies in the peer-reviewed scientific literature are observational or retrospectively conducted with small populations. Although well-established motility testing methods exist, studies are not designed to provide comparison of the accuracy—including sensitivity, specificity, positive and negative predictive values—of the SmartPill to conventional tests as the reference standard in same symptomatic patient population. As a result no strong conclusions can be made regarding the clinical utility of this technology (Kuo, 2011; Rao, 2011a; Camilleri, 2010; Kloetzer, 2010; Sarosiek, 2010; Rao, 2009; Hasler, 2009; Kuo, 2008).

### **Professional Societies/Organizations**

**American College of Gastroenterology (ACG):** The ACG Practice Guideline on Gastroparesis (Camilleri et al. 2013) notes that wireless capsule motility testing is an alternative approach for assessment of gastric emptying; however, further validation is required before it can be considered an alternate to scintigraphy for the diagnosis of gastroparesis. This is noted to be a 'Conditional recommendation, moderate level of evidence'.

**American Gastroenterological Association (AGA):** The AGA Medical Position Statement 'Diagnosis and Treatment of Gastroparesis' (Parkman, et al., 2004) states that GES of a radiolabeled solid meal is the best accepted method to test for delayed gastric emptying. The AGA Medical Position Statement Guidelines on Constipation (AGA, 2013) supports the use of special tests such as CTT, anorectal manometry, balloon-expulsion tests or defecography in refractory patients. Neither guideline addresses the use of SmartPill.

**American and European Neurogastroenterology and Motility Societies:** These organizations published guidelines with consensus recommendations on the indications and optimal methods for the use of transit measurements in clinical practice (Rao, et al., 2011b). The guidelines note that, "The WMC (wireless motility capsule) is a validated and standardized test. It is recommended for assessment of colonic transit time in subjects with constipation and those with suspected colonic disorders. It also provides measurements of regional and whole gut transit."

**American Society of Colon and Rectal Surgeons (ASCRS):** The ASCRS practice parameter for the evaluation and management of constipation notes that anorectal physiology and colon transit time investigations may help to identify the underlying etiology and improve the outcome in patients with refractory constipation. The practice position notes the measurement of colon transit time using radio-opaque markers in patients with suspected slow-transit constipation is inexpensive, simple, and safe (Ternent, et al., 2007).

**North American Society for Pediatric Gastroenterology, Hepatology and Nutrition (NASPGHN):** The NASPGHN recommendations on evaluation and treatment of constipation in infants and children (2006) notes that an evaluation of colonic transit time with radiopaque markers may be helpful in children with a history of infrequent bowel movements who have no objective findings of constipation.

### Use Outside of the US

National Institute for Health and Care Excellence (NICE): NICE published guidelines regarding assessing motility of the gastrointestinal tract using a wireless capsule. The guidelines note that:

- The evidence on assessing motility of the gastrointestinal tract using a wireless capsule raises no major safety concerns.
- There is evidence of efficacy in measuring gastrointestinal function but uncertainty about the clinical benefit of this, and about patient selection; therefore, this procedure should be used only with special arrangements for clinical governance, consent and audit or research.

#### **High Resolution Anoscopy (HRA) (CPT Codes 46601, 46607)**

During an anoscopy the perianal area and distal rectum are examined. High resolution anoscopy has been proposed as a method to identify anal lesions in high-risk populations, and for use in screening for anal cytology. High resolution anoscopy uses an anoscope as well as a colonoscope or operating microscope for more detailed examination. After application of a 3% acetic acid solution and Lugol's iodine, the canal is inspected with the colonoscope. Areas with acetowhitening are examined for abnormal patterns and targeted biopsies are performed on areas suspicious for high-grade squamous intraepithelial lesion (HSIL). Correlation of biopsy results with anal cytology results has been variable (Lee, 2010).

#### **Literature Review**

Hayes published a directory report for high-resolution anoscopy (HRA) for the evaluation of anal lesions (2014; 2017). The report concluded that HRA exhibits high sensitivity and moderate specificity for detecting abnormal lesions in high-risk populations. The findings included that HRA is more sensitive than cytology in detecting potentially harmful lesions. There were few studies found that evaluated the capacity of HRA to detect high grade anal intraepithelial neoplasia and findings were too inconsistent to accurately make any determination regarding the validity of HRA for this use.

Randomized controlled clinical trial data are lacking to demonstrate improved health outcomes with the use of high-resolution anoscopy to detect anal cytology. However, there is support by a number of professional societies/organizations related to its use as diagnostic tool in individuals with a suspicious anal lesion, including high-grade suspicious intraepithelial lesion (HSIL) and anal dysplasia found in prior cytology/biopsy.

A case series by Chang (2002) reported on a prospective study of high resolution anoscopy directed surgery in 37 patients with high-grade squamous intraepithelial lesion. Twenty-nine patients tested positive for human

immunodeficiency virus (HIV), eight patients tested negative. Mean follow-up was 32.3 months for HIV-positive patients and 28.6 months in HIV-negative patients. No HIV-negative patient developed recurrent high-grade squamous intraepithelial lesions. Twenty-three of 29 HIV positive patients had persistent or recurrent high-grade squamous intraepithelial lesions (HSIL) ( $p < .003$ ). Six patients underwent reoperation for HSIL; four recurred by six months. No patients developed incontinence, stenosis, postoperative infection, or significant bleeding after surgical treatment. Study limitations include small patient population and uncontrolled study design.

#### **Professional Societies/Organizations**

**American Society of Colon and Rectal Surgeons (ACRS):** The ACRS (Steele, et al., 2012) published practice parameters for anal squamous neoplasms. The guideline notes that targeted destruction guided by high resolution anoscopy is effective to identify, biopsy, and destroy low grade anal intraepithelial neoplasm [LGAIN]/high grade anal epithelial neoplasm [HGAIN] without the morbidity associated with wide local excision. The Guidelines also note that a comprehensive approach with cytology, high resolution anoscopy, targeted biopsies, and directed therapy has reported clearance of high grade anal intraepithelial neoplasm [HGAIN] in up to 80%, with progression to higher-grade disease and invasive cancer in less than 5%. Therefore, expectant management with close follow-up may be considered in select cases depending on risk factors, comorbidities, and available resources. However, because of the high prevalence of concomitant cervical intraepithelial neoplasm, a referral to gynecology is recommended to complete the evaluation. Targeted destruction and close clinical long-term follow-up is appropriate therapy for LGAIN/HGAIN. (Grade of Recommendation: Strong recommendation based on low-quality evidence, 1C)

#### **Use Outside of the US**

**Ontario Health Technology Assessment Series (OHTAS):** OHTAS (2007) notes that high resolution anoscopy rather than routine anoscopy-guided biopsy is considered to be the diagnostic standard.

#### **13C-Spirulina Gastric Emptying Breath Test (GEBT) (CPT code 91299)**

Gastroparesis is a syndrome of objectively delayed gastric emptying in the absence of a mechanical obstruction and cardinal symptoms of nausea, vomiting, early satiety, bloating, and/or upper abdominal pain. In patients with suspected gastroparesis and no evidence of a mechanical obstruction on imaging or upper endoscopy, an assessment of gastric motility is necessary to establish the diagnosis of gastroparesis. Delayed gastric emptying on scintigraphy is required to establish the diagnosis of gastroparesis (Camilleri, [UpToDate], 2016). A more recently developed test, the 13C-Spirulina Gastric Emptying Breath Test (GEBT) (Cairn Diagnostics, Brentwood, TN) has been proposed as an alternative approach for the assessment of gastric emptying. While this test has the advantage of avoiding radiation associated with scintigraphy, further studies are needed before they can be routinely recommended for evaluation of delayed gastric emptying (Camilleri, [UpToDate], 2016).

A kit containing the specially labeled test meal and all components necessary to administer the test meal and collect breath samples is provided to the test administration site by Cairn Diagnostics. The collected breath samples are returned to Cairn's CLIA-certified clinical laboratory for analysis by gas isotope ratio mass spectrometry (GIRMS). The patient will eat a special test meal, and then additional breath samples are collected at specified times. Once the test meal is consumed, the carbon-13 in the Cairn GEBT test meal gives rise to carbon-13 labeled CO<sub>2</sub>, or <sup>13</sup>CO<sub>2</sub>, which can be measured in the breath samples.
